Even at midcycle, she wears white with confidence

Only Tri-Norinyl provides a full 1 mg of progestin at the midcycle (days 8–16), when clinical data indicate that breakthrough bleeding and spotting are most likely to occur.[1]

To help control midcycle breakthrough bleeding: make the midcycle the high point of protection.

Extra midcycle progestin to reduce midcycle breakthrough bleeding

9 DAYS
1.0 mg norethindrone

7 DAYS
0.5 mg norethindrone

5 DAYS
0.5 mg norethindrone

21 DAYS *0.035 mg ethinyl estradiol*

TRI-NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

1. Data available from Syntex Laboratories, Inc., document #92363.

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. Before prescribing Tri-Norinyl, please see brief summary of prescribing information on following page.

NORINYL® 1 + 80 21-Day Tablets (norethindrone 1 mg with mestranol 0.08 mg)

NORINYL® 1 + 80 28-Day Tablets (21 norethindrone 1 mg with mestranol 0.08 mg tablets followed by 7 inert tablets)

NORINYL® 2 mg Tablets (norethindrone 2 mg with mestranol 0.1 mg)

NOR-Q.D.® (norethindrone) Tablets 0.35 mg

ORAL CONTRACEPTIVE (O.C.) AGENTS

Indications Prevention of pregnancy. *DOSE-RELATED RISK OF THROMBOEMBOLISM.* **Because** studies have shown a positive association between OC estrogen dose and risk of thromboembolism, it is prudent to minimize estrogen exposure. Prescribe an OC with the least amount of estrogen compatible with an acceptable pregnancy rate and patient acceptance. Start new users on OCs containing 0.05 mg or less of estrogen.

Contraindications 1. Known or suspected pregnancy (see Warning #5). 2. Thrombophlebitis or thromboembolic disorders. 3. Past history of deep vein thrombophlebitis or thromboembolic disorders. 4. Undiagnosed abnormal genital bleeding. 5. OCs should not be used by women who have or have had any of the following: a. cerebral vascular or coronary artery disease, including myocardial infarction. b. known or suspected carcinoma of the breast. c. known or suspected estrogen dependent neoplasia. d. benign or malignant liver tumor that developed during use of OCs or other estrogen containing products.

WARNINGS: Cigarette smoking increases the risk of serious cardiovascular side effects from OC use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use OCs should be strongly advised not to smoke.

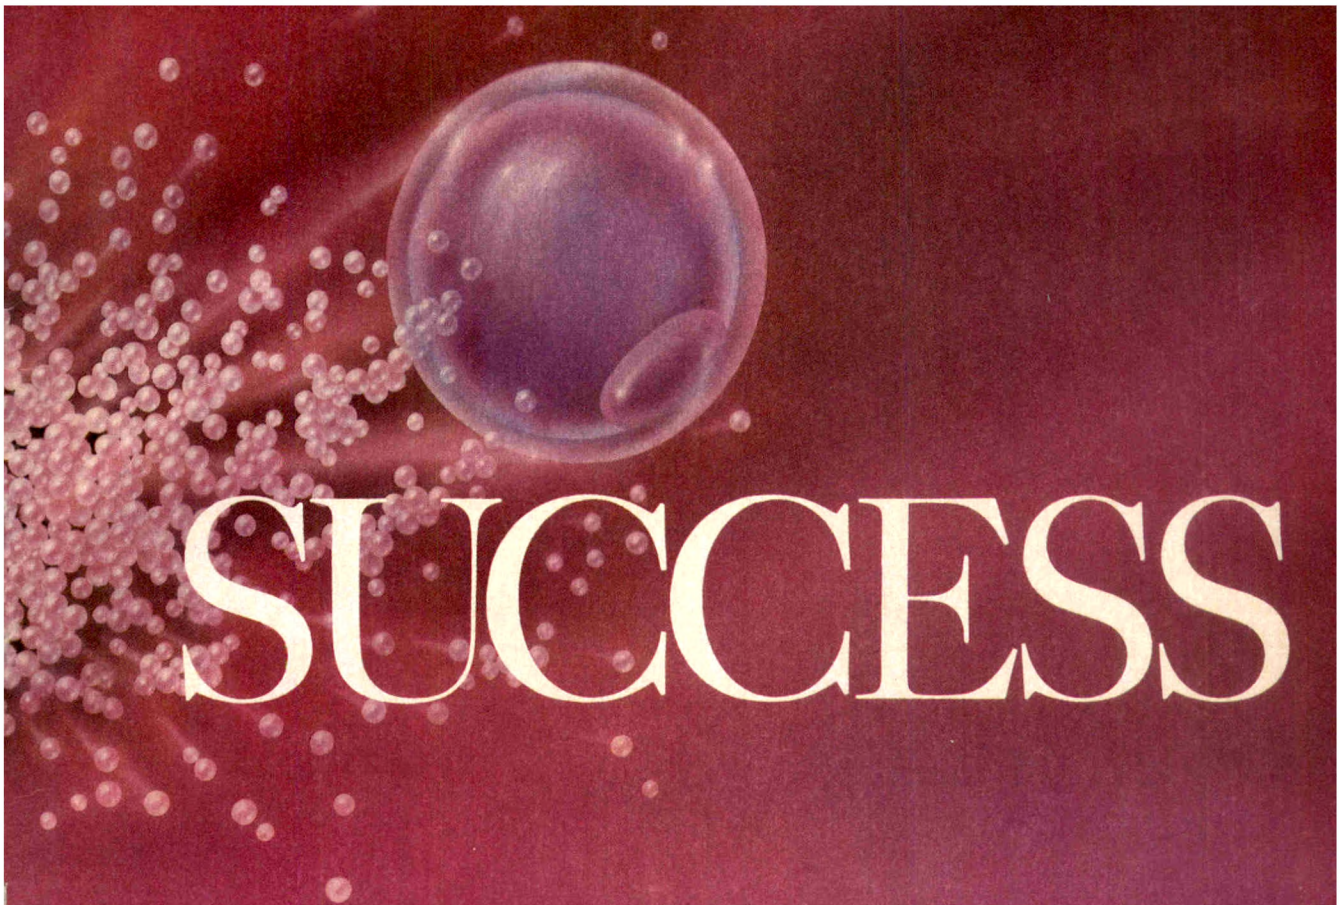
The use of OCs is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, liver tumor, gall bladder disease, visual disturbances, fetal abnormalities, and hypertension. Practitioners prescribing OCs should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with OC use is established. One study demonstrated an increased relative risk for fatal venous thromboembolism and several studies demonstrated it for non-fatal venous thromboembolism. They estimate that OC users are 4-11 times more likely than nonusers to develop these diseases without evident cause. One British study reported an excess death rate of 40% in OC users, most of which resulted from cardiovascular disease. Another British study showed a lower death rate in OC users than controls; an increase in cardiovascular deaths was seen but was not statistically significant. A U.S. prospective study failed to disclose increased mortality rates from cardiovascular disorders, but a subset analyzed as a retrospective, case-control study showed significant increases in venous thromboembolism. CEREBROVASCULAR DISORDERS. Two American studies demonstrated an increased relative risk for stroke not shown in prior British studies. In an American study of cerebrovascular disorders in women with and without predisposing causes, relative risk of hemorrhagic stroke was estimated as 2.0 times greater and thrombotic stroke as 4-9.5 times greater in users than nonusers. A British long-term follow-up study reported in 1976 a highly significant association between OC use and stroke. Another study had suggested an association in 1974, but the number of cases was too small to estimate the risk. Subarachnoid hemorrhage has been shown to be increased by OC use in British and American studies. Smoking alone increases incidence of these accidents; smoking and pill use appear to increase risk more than either alone.

MYOCARDIAL INFARCTION (MI). Increased relative risk of MI associated with OC use has been reported. One British study found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing MI, regardless of OC use. OCs were an additional risk factor. In terms of relative risk, it has been estimated that nonsmoking OC users (smoking is considered a major predisposing condition to MI) are twice as likely to have a fatal MI as nonsmoking nonusers. OC users who are smokers have a 5-fold increased risk of fatal infarction compared to nonsmoking users, and a 10-12-fold increased risk compared to nonsmoking nonusers. The number of cigarettes smoked is important. In determining the importance of these relative risks, baseline rates for various age groups must be considered. (Estimates are based on British vital statistics which show acute MI death rates 2-3 times less than in the U.S. so U.S. death rates could be higher.) Importance of other predisposing conditions in determining relative and absolute risks has not been quantified; other synergistic actions may exist. RISK OF DOSE. Using data from several national adverse reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to estrogen dose in OCs. OCs with 0.1 mg or more of estrogen were associated with a higher risk of thromboembolism than those containing 0.05-0.08 mg but quantity of estrogen may not be the sole factor. This was supported by a U.S. study. A British study found a positive association between dose of progestogen or estrogen and certain thromboembolic conditions. Swedish authorities noted decreased reporting of thromboembolic episodes when higher estrogen preparations were no longer prescribed. Careful epidemiological studies to determine degree of thromboembolic disease risk associated with progestogen-only OCs have not been done. Thromboembolic disease has been reported in women using these products, and they should not be considered free of excess risk. PERSISTENCE OF RISK. Two studies have suggested an increased risk may persist for 6 years after discontinuation of OC use for cerebrovascular disease and 9 years for MI; another study suggested the persistence of risk for subarachnoid hemorrhage. ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES. A large British prospective study estimated mortality rate per 100,000 women per year from circulatory system diseases for OC users and nonusers according to age, smoking habits, and duration of use. The overall annual excess death rate for OC users was estimated to be 20/100,000 (ages 15-34–5/100,000; ages 35-44–33/100,000; ages 45-49–140/100,000). Risk is concentrated in long-term users and in smokers, and may persist after OC discontinuation. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all occurred in women 35 or older. An update provided the following rates: ages 15-34–1/6700 for nonsmokers and 1/2000 for smokers; ages 45 and over–1/2500 for nonsmokers and 1/500 for smokers. Risk appeared to increase with parity, but not with duration of use. Until more women under 35 with continuous use for 5 or more years are available, it is not possible to assess relative risk for this age group. Data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. Estimates include combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease for OCs) plus risk attributable to pregnancy or abortion if the method fails (which varies with the effectiveness of the contraceptive method). The study concluded that mortality associated with all contraceptive methods is below that of childbirth, except for OCs in women over 40 who smoke. (Rates given for pill only/smokers for each age are for smokers as a class. For "heavy" smokers (more than 15 cigarettes a day), the rates would be about double; for "light" smokers (less than 15), about half.) The lowest mortality is with the condom or diaphragm backed up by early abortion. The study also concluded that OC users who smoke, especially over 30, have greater mortality risk than OC users who do not smoke.

Risk of thromboembolic and thrombotic disease associated with OCs increases with age after 30 and for MI is further increased by hypertension, hyperlipidemias, obesity, diabetes, or history of preeclamptic toxemia, and especially by smoking. The following chart gives a gross estimate of risk of death from circulatory disorders associated with OC use.

SMOKING HABITS AND OTHER PREDISPOSING CONDITIONS–RISK ASSOCIATED WITH USE OF OCs



Age	Below 30	30-39	40 +
Heavy smokers	C	B	A
Light smokers	D	C	B
Nonsmokers (no predisposing conditions)	D	C,D	C
Nonsmokers (other predisposing conditions)	C	C,B	B,A

A–Use associated with very high risk
B–Use associated with high risk
C–Use associated with moderate risk
D–Use associated with low risk

Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, discontinue OC immediately. A 4-6 fold increased risk of post-surgery thromboembolic complications has been reported in OC users. If feasible, discontinue OCs at least 4 weeks before surgery associated with increased risk of thromboembolism or prolonged immobilization. Before resuming OC after major surgery or bedrest, balance risks of post-surgery thromboembolic complications with contraceptive needs. Data suggest varicose veins substantially increase risk of superficial venous thrombosis of the leg, the risk depending on the severity of the varicosities. 2. *Ocular Lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OC use. Discontinue OC if there is unexplained, sudden, or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions; and institute appropriate diagnostic and therapeutic measures. 3. *Carcinoma:* Long-term continuous administration of natural or synthetic estrogen in certain animals increases certain tumors, benign or malignant, such as breast, cervix, vagina, uterus, ovary, pituitary and liver. Certain synthetic progestogens, none currently in OCs, increase the incidence of mammary nodules, benign and malignant, in dogs. Several retrospective case-control studies reported an increased relative risk (3.1-13.9 times) associating endometrial carcinoma with the prolonged use of estrogens in postmenopausal women. One publication reported the first 30 cases submitted to the registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the adenocarcinomas found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding when OCs were first given, polycystic ovaries), nearly all occurred in women who had used sequential OCs, which are no longer marketed. No statistical association has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs, although individual cases have been reported. Studies have shown no increased risk of breast cancer to OC or estrogen users. One study found no overall increased risk of breast cancer in OC users but a greater risk was suggested for OC users with documented benign breast disease and for long-term (2-4 years) users. Another study found a history of breast cancer among grandmothers or aunts was significantly more frequent among breast cancer patients who had used an OC continuously for one or more years than among nonusers with breast cancer. One other study indicated an increasing risk of breast cancer in women taking menopausal estrogens, which increased with duration of follow-up. One author suggests that extended (over 6 years) OC use prior to first full term pregnancy was associated with a significant relative risk of breast cancer, and other studies suggested an increased risk of breast cancer with long-term OC use before age 25. A reduced occurrence of benign breast tumors in OC users has been well documented. One study reported malignant melanoma more frequently in OC users than controls and suggests an increased incidence of urinary tract and thyroid cancers. A prospective study of women with cervical dysplasia found an increase in severity and conversion to cancer *in situ* in OC users compared to nonusers. This became statistically significant after 3-4 years of use. Nonreversal of dysplasia within the first 6 months of pill use was suggested to predict progression after prolonged exposure. One study disclosed an increased risk of cancer of the cervix (largely carcinoma *in situ*) in OC users under 40, particularly those who had used OCs over 4 years. Two other studies suggested an increasing incidence of cervical neoplasms with longer duration of OC use. There have been other reports of microglandular hyperplasia of the cervix in OC users. One study reported an association between OC use and endocervical adenocarcinoma. In summary, there is no confirmed evidence from human studies of increased risk of cancer associated with OCs. Close clinical surveillance of all OC users is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, take appropriate diagnostic measures to rule out malignancy. Monitor OC users with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms with particular care. (See also Warnings, 4. *Liver Tumors.*) 4. *Liver Tumors:* Sudden severe abdominal pain or shock may be due to rupture and hemorrhage of a liver tumor. There have been reports associating benign or malignant liver tumors with short-term and long-term OC use. One study reported use of OCs with high hormonal potency and age over 30 may further increase risk of hepatocellular adenoma. Two studies relate risk with duration of use, risk being much greater after 4 or more years of use. Long-term OC users have an estimated annual incidence of hepatocellular adenoma of 3-4/100,000. Although an uncommon lesion, it should be considered in women presenting with an "acute abdomen". The tumor may cause serious or fatal hemorrhage. Patients with liver tumors have demonstrated variable clinical features which may make preoperative diagnosis difficult. Some cases presented because of right upper quadrant masses, while most had signs and symptoms of acute intraperitoneal hemorrhage. Routine radiological and laboratory studies may not be helpful. Liver scans may show a focal defect. Hepatic arteriography may be useful in diagnosing primary liver neoplasm. Cases of hepatocellular carcinoma have been reported in long-term users of OCs.[105-107] An epidemiological study suggested a 4-fold increase in relative risk for hepatocellular carcinoma in OC users for 8 years or more, which increased to 7 in women with markers of hepatitis B. A second study suggested a risk of about 20 for use in excess of 8 years. 5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring:* Use of female sex hormones–estrogenic and progestational agents–during early pregnancy may seriously damage the offspring. Females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1/1000 exposures or less. Although there is no evidence that OCs further enhance the risk of developing this type of malignancy, such OC users should be monitored with particular care. A high percentage of women exposed to diethylstilbestrol (30-90%) have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are a precursor of vaginal malignancy. Male children so exposed may develop urogenital tract abnormalities. Although similar data are not available on other estrogens, it cannot be presumed that they would not induce similar changes. Increased risk of congenital anomalies, including heart and limb defects, has been reported following use of sex hormones, including OCs, in pregnancy. One case-control study estimated a 4.7-fold increased relative risk of limb-reduction defects in infants exposed *in utero* to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some exposures involved only a few days of treatment. Data suggest risk of limb-reduction defects in exposed fetuses is somewhat less than 1/1000 live births. In a large prospective study, cardiovascular defects in children born to women who received female hormones, including OCs, during early pregnancy occurred at 18.2/1000 births, compared to 7.8/1000 for children not so exposed *in utero*. These results are statistically significant. A Welsh study found a statistically significant excess of neural tube defects among offspring of prior OC users (within 3 months) than among controls. The incidence of twin births may be increased for women who conceive shortly after discontinuing OC use. In the past, female sex hormones were used during pregnancy in an attempt to treat threatened or habitual abortion. There is evidence that estrogens are ineffective, and there is no evidence from well controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. If the patient has not adhered to the prescribed schedule, consider possible preg
nancy at the first missed period (or 45 days from the last menstrual period if
progestogen-only OCs are used) and discontinue OC use until pregnancy has
been ruled out. For any patient who has missed two consecutive periods, rule
out pregnancy before continuing the OC. If pregnancy is confirmed, tell th
patient about potential risks to the fetus and discuss advisability of continuit
the pregnancy. Women who discontinue OCs to become pregnant should use
alternate form of contraception for a period of time before attempting to c
ceive. A 3-month period is supported by a study suggesting increased frequen
of neural tube defects in women impregnated during the first 3 months aft
cessation of OC use. Do not use progestogen-only or progestogen-estroge
combinations to induce withdrawal bleeding as a pregnancy test. 6. *Gall Bladde
Disease:* Studies report increased risk of gall bladder disease in OC or estroge
users. In one study, an increased risk appeared after 2 years of use and double
after 4-5 years; in another study, an increased risk was apparent between 6 an
12 months. 7. *Carbohydrate and Lipid Metabolic Effects:* Because a decrease
glucose tolerance has been observed in a significant percentage of patients
OCs, prediabetic and diabetic OC users should be carefully observed. An increa
in triglycerides and total phospholipids has been observed in OC users but i
clinical significance is unknown. 8. *Elevated Blood Pressure:* An increase
blood pressure has been reported with OC use. Hypertension may occur within
few months of beginning OCs. In the first year of use, incidence of hypertensio
may be no higher in OC users than in nonusers. Incidence in users increases wit
exposure and in the fifth year of use is 2.5-3 times that in the first year. Age
strongly correlated with hypertension in OC users. Women with a history
elevated blood pressure (hypertension), preexisting renal disease, history
toxemia or elevated blood pressure during pregnancy, familial tendency to hype
tension or its consequences, or history of excessive weight gain or fluid retentio
during the menstrual cycle may be more likely to develop elevated blood pressur
when given OCs and should be monitored closely. Even though elevated blooc
pressure may remain within the "normal" range, closely watch elevations, partic
ularly for women with other risk factors for cardiovascular disease or stroke. High
blood pressure may or may not persist after OC discontinuation. 9. *Headache:*
Discontinue OC and evaluate the cause of onset or exacerbation of migraine or
development of a new pattern of headache which is recurrent, persistent, or
severe. 10. *Bleeding Irregularities:* Breakthrough bleeding, spotting, and missed
menses often make users discontinue OCs. In breakthrough bleeding, as in all
cases of irregular bleeding from the vagina, consider nonfunctional causes. In
undiagnosed persistent or recurrent abnormal bleeding from the vagina, use
adequate diagnostic measures to rule out pregnancy or malignancy. If pathology
has been excluded, time or another formulation may solve the problem. While
potentially useful in minimizing menstrual irregularity, change to an OC with
higher estrogen content only if necessary since this may increase the ris
thromboembolic disease. Women with a history of oligomenorrhea or secon
amenorrhea or young women without regular cycles may tend to remain a
latory or to become amenorrheic after OC discontinuation. Women with
preexisting problems should be advised of this and encouraged to use
contraceptive methods. Post-use anovulation, possibly prolonged, may occ
women without previous irregularities. A higher incidence of galactorrhea a
pituitary tumors (e.g., adenomas) has been associated with amenorrhe
former users compared with nonusers. One study reported a 16-fold incre
incidence of pituitary prolactin-secreting tumors among patients with po
amenorrhea when galactorrhea was present. 11. *Infertility:* There is evide
impairment of fertility in women discontinuing OCs in comparison with
contraceptive methods, which appears to be independent of duration
While impairment diminishes with time, there is an appreciable differenc
results in nulliparous women for OC and other groups 30 months after di
uation of birth control. For parous women the difference is not appar
months after cessation of contraception. One study suggests that the inc
of *Chlamydia trachomatis* infection, the leading cause of nongonococcal P
increased by OCs. 12. *Ectopic Pregnancy:* Ectopic as well as intrauterin
nancy may occur in OC failure. In progestogen-only OC failures, the
ectopic to intrauterine pregnancies is higher than in nonusers, since
are more effective in preventing intrauterine than ectopic pregnancies.
Feeding: OCs in the postpartum period may interfere with lactation by
ing quantity and quality of breast milk. A small fraction of OC hormona
has been identified in milk of mothers receiving OCs. Effects, if any,
breast-fed child have not been determined. If feasible, defer OC use
infant has been weaned. **Precautions** *GENERAL* 1. Take a complete medi
family history before starting OCs. Pretreatment and periodic physical
should include special reference to blood pressure, breasts, abdomen and
organs, including Papanicolaou smear and relevant lab tests. As a gener
OCs should not be prescribed for longer than 1 year without another physi
Under the influence of estrogen-progestogen preparations, preexisting
leiomyomata may enlarge. 3. Observe patients with a history of psychic d
sion and discontinue OCs if depression recurs to a serious degree. Pa
becoming significantly depressed while taking OCs should stop the OC ar
an alternate method of contraception to determine whether the symptom i
related. 4. OCs may cause some fluid retention. Prescribe with caution, an
with careful monitoring, in patients with conditions that might be aggrava
fluid retention, such as convulsive disorders, migraine syndrome, asth
cardiac, hepatic or renal insufficiency. 5. Patients with a past history of jau
during pregnancy have an increased risk of recurrence while using OCs. D
tinue OC if jaundice develops. 6. Steroid hormones may be poorly metaboliz
patients with impaired liver function and should be administered with cauti
such patients. 7. OC users may have disturbances in normal tryptophan me
lism that may result in a relative pyridoxine deficiency. The clinical significa
unknown. 8. Serum folate levels may be depressed by OC use. Since the pe
woman is predisposed to folate deficiency and incidence of folate defic
increases with increasing gestation, if a woman becomes pregnant shortly
stopping OCs, she may have a greater chance of developing folate deficienc
related complications. 9. Advise the pathologist of OC use when relevant
mens are submitted. 10. Certain endocrine and liver function tests and
components may be affected by estrogen-containing OCs. For exar
Increased: sulfobromophthalein retention. b. Increased prothrombin an
VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine
platelet aggregability. c. Increased thyroid binding globulin (TBG) lea
increased circulating total thyroid hormone, as measured by protein-
iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin upt
decreased, reflecting the elevated TBG; free T4 concentration is unalter
Decreased pregnanediol excretion. e. Reduced response to metyrapone t
Increased phospholipids and triglycerides. g. Temporarily decreased gl
tolerance. 11. Contact lens wearers who develop visual changes or chang
lens tolerance should be assessed by an ophthalmologist and remain
permanent cessation of wear considered. DRUG INTERACTIONS. OCs m
less effective and there may be increased breakthrough bleeding from in
tions with rifampin, isoniazid, ampicillin, tetracycline, neomycin, penicil
chloramphenicol, sulfonamides, nitrofurantoin, barbiturates, phenytoin,
done, analgesics, tranquilizers, antimigraine preparations, antihistamines,
griseofulvin. OCs may alter effectiveness of such other drugs as oral antico
lants, anticonvulsants, tricyclic antidepressants, antihypertensive agents
guanethidine), vitamins, hypoglycemic agents, tranquilizers, hypnotic prep
tions, theophylline, and beta blockers. Toxic liver effects have been reported
a combination of an OC and cyclosporin A. *CARCINOGENESIS* See Warni
PREGNANCY Pregnancy category X. See Contraindications and Warni
NURSING MOTHERS See Warnings. **Adverse Reactions** An increased risk of
following serious adverse reactions has been associated with OC use (see W
ings): thrombophlebitis, thrombosis, pulmonary embolism, coronary throm
sis, cerebral thrombosis, mesenteric thrombosis, liver tumors, cereb
hemorrhage, hypertension, gall bladder disease, congenital anomalies, ne
ocular lesions, e.g., retinal thrombosis and optic neuritis, Budd-Chiari syndro
Raynaud's disease, arterial thromboembolism. The following adverse reacti
have been reported in OC users and are believed to be drug related: bleed
irregularities (breakthrough bleeding, spotting, missed menses during treatm
amenorrhea after treatment), gastrointestinal symptoms (nausea, vomit
bloating, abdominal cramps, colitis), dysmenorrhea, infertility after discont
ance of treatment, edema, chloasma or melasma which may persist after drug
discontinued, breast changes (tenderness, enlargement, and secretion), intole
ance to contact lenses, changes in corneal curvature (steepening), change
weight (increase or decrease), change in cervical erosion and cervical secretion
possible diminution of lactation when given immediately postpartum, cholestati
jaundice, migraine, increase in size of uterine leiomyomata, rash (allergic), me
tal depression, reduced tolerance to carbohydrates, vaginal candidiasis, prola
tin-secreting pituitary tumors, chilblains. The following adverse reactions ha
been reported in OC users and the association has been neither confirmed
refuted: premenstrual-like syndrome, cataracts, changes in libido, chore
changes in appetite, cystitis-like syndrome, headache, nervousness, dizzine
hirsutism, loss of hair, erythema multiforme, erythema nodosum, hemorrha
eruptions, vaginitis, porphyria, impaired renal function, malignant nephrosc
rosis (hemolytic uremic syndrome), malignant hypertension, acute renal failu
premature supraventricular contractions. **Information for the Patient** (See Pati
Package Insert).

SYNTEX

SUCCESS

When pregnancy is the goal, successful ovulation is the first hurdle. Serophene has demonstrated its effectiveness for six years—with ovulation rates of 50% to 94% and pregnancy rates of 11% to 52%.

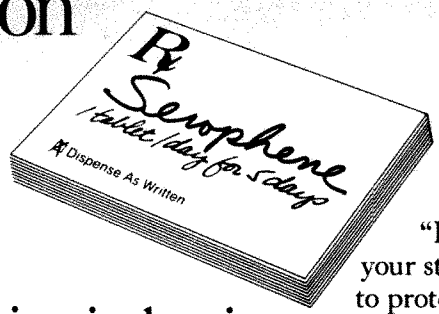
For effective first-line ovulation-induction therapy, success starts with Serophene.

Starts with SEROPHENE®

(clomiphene citrate tablets, USP) 50 mg

The first choice for ovulation induction

8, Serono Laboratories, Inc.



e see brief summary of prescribing information on adjacent page.

The World Leader in Infertility Therapy

Serono

Successful ovulation starts with SEROPHENE®

(clomiphene citrate tablets, USP) 50 mg

Be sure your patients receive the drug you prescribe. Specify "Dispense as Written" or your state's approved wording to protect the integrity of your Serophene prescription.

The first choice for ovulation induction

Serophene®
(clomiphene citrate tablets, USP)
Brief Summary:
Indications:
Clomiphene citrate is indicated for the treatment of ovulatory failure in patients desiring pregnancy, and whose husbands are fertile and potent. Impediments to this goal must be excluded or adequately treated before beginning therapy. Administration of clomiphene citrate is indicated only in patients with demonstrated ovulatory dysfunction and in whom the following conditions apply:
1. Normal liver function.
2. Physiologic indications of normal endogenous estrogen (as estimated from vaginal smears, endometrial biopsy, assay of urinary estrogen, or from bleeding in response to progesterone). Reduced estrogen levels, while less favorable, do not prevent successful therapy.
3. Clomiphene citrate therapy is not effective for those patients with primary pituitary or ovarian failure. It cannot substitute for appropriate therapy of other disturbances leading to ovulatory dysfunction, e.g., diseases of the thyroid or adrenals.
4. Particularly careful evaluation prior to clomiphene citrate therapy should be done in patients with abnormal uterine bleeding. It is most important that neoplastic lesions are detected.

Contraindications:
Pregnancy
Although no direct effect of clomiphene citrate therapy on the human fetus has been seen, clomiphene citrate should not be administered in cases of suspected pregnancy as such effects have been reported in animals. To prevent inadvertent clomiphene citrate administration during early pregnancy, the basal body temperature should be recorded throughout all treatment cycles, and therapy should be discontinued if pregnancy is suspected. If the basal body temperature following clomiphene citrate is biphasic and is not followed by menses, the possibility of an ovarian cyst and/or pregnancy should be excluded. Until the correct diagnosis has been determined, the next course of therapy should be delayed.
Liver Disease
Patients with liver disease or a history of liver dysfunction should not receive clomiphene citrate therapy.
Abnormal Uterine Bleeding
Clomiphene citrate is contraindicated in patients with abnormal uterine bleeding.

Warnings:
Visual Symptoms
Patients should be warned that blurring and/or other visual symptoms may occur occasionally with clomiphene citrate therapy. These may make activities such as driving or operating machinery more hazardous than usual, particularly under conditions of variable lighting. While their significance is not yet understood (see ADVERSE REACTIONS), patients having any visual symptoms, should discontinue treatment and have a complete ophthalmologic evaluation.

Precautions:
Diagnosis Prior to Clomiphene Citrate Therapy
Careful evaluation should be given to candidates for clomiphene citrate therapy. A complete pelvic examination should be performed prior to treatment and repeated before each subsequent course. Clomiphene citrate should not be given to patients with an ovarian cyst, as further ovarian enlargement may result.
Since the incidence of endometrial carcinoma and of ovulatory disorders increases with age, endometrial biopsy should always exclude the former as causative in such patients. If abnormal uterine bleeding is present, full diagnostic measures are necessary.
Ovarian Overstimulation During Treatment with Clomiphene Citrate
To minimize the hazard associated with the occasional abnormal ovarian enlargement during clomiphene citrate therapy (see ADVERSE REACTIONS), the lowest dose producing good results should be chosen. Some patients with polycystic ovary syndrome are unusually sensitive to gonadotropin and may have an exaggerated response to usual doses of clomiphene citrate. Maximal enlargement of the ovary, whether abnormal or physiologic, does not occur until several days after discontinuation of clomiphene citrate. The patient complaining of pelvic pains after receiving clomiphene citrate should be examined carefully. If enlargement of the ovary occurs, clomiphene citrate therapy should be withheld until the ovaries have returned to pretreatment size, and the dosage or duration of the next course should be reduced. The ovarian enlargement and cyst formation following clomiphene citrate therapy regress spontaneously within a few days or weeks after discontinuing treatment. Therefore, unless a strong indication for laparotomy exists, such cystic enlargement always should be managed conservatively.
Multiple Pregnancy
In the reviewed publications, the incidence of multiple pregnancies was increased during those cycles in which clomiphene citrate was given. Among the 1803 pregnancies on which the outcome was reported, 90% were single and 10% twins. Less than 1% of the reported deliveries resulted in triplets or more.
Of these multiple pregnancies, 96-99% resulted in the births of live infants. The patient and her husband should be advised of the frequency and potential hazards of multiple pregnancy before starting treatment.

Adverse Reactions:
Symptoms
Side effects are not prominent at the recommended dosage of clomiphene citrate, and infrequently interfere with treatment. Side effects tend to occur more frequently at higher doses and in the longer treatment courses used in some early studies. The more common side effects and the percent of patients experiencing them include vasomotor flushes (11%), abdominal discomfort (7.4%), abnormal uterine bleeding (0.5%), ovarian enlargement (14%), breast tenderness (2.1%), and visual symptoms (1.6%). The vasomotor symptoms resemble menopausal "hot flushes," and are not usually severe. They promptly disappear after treatment is discontinued. Abdominal discomfort may resemble ovulatory (mittelschmerz) or premenstrual phenomena, or that due to ovarian enlargement. In addition, nausea and vomiting (2.1%), nervousness and insomnia (1.9%), headache (1%), dizziness and lightheadedness (1%), increased urination (0.9%), depression and fatigue (0.8%), urticaria and allergic dermatitis (0.6%), weight gain (0.4%), and reversible hair loss (0.3%) have been reported.
When clomiphene citrate is administered at the recommended dose, abnormal ovarian enlargement (see PRECAUTIONS) is infrequent, although the usual cyclic variation in ovarian size may be exaggerated. Similarly, mid-cycle ovarian pain (mittelschmerz) may be accentuated. With prolonged or higher dosage, ovarian enlargement and cyst formation (usually luteal) may occur more often and the luteal phase of the cycle may be prolonged. Patients with polycystic ovary disease may be unusually sensitive to clomiphene therapy. Rare occurrences of massive ovarian enlargement have been reported, for example, in a patient with polycystic ovary syndrome whose clomiphene citrate therapy consisted of 100 mg daily for 14 days. Since abnormal ovarian enlargement usually regresses spontaneously, most of these patients should be treated conservatively.
The incidence of visual symptoms (see WARNINGS for further recommendations), usually described as "blurring" or spots or flashes (scintillating scotomata), correlates with increasing total dose. The symptoms disappear within a few days or weeks after clomiphene citrate is discontinued. This may be due to intensification and/or prolongation of afterimages. Symptoms often appear first, or are accentuated, upon exposure to a more brightly lit environment. While measured visual acuity has not generally been affected, in one patient taking 200 mg daily, visual blurring developed on the seventh day of treatment, and progressed to severe diminution of visual acuity by the tenth day. No other abnormality was coincident, and the visual acuity was normal by the third day after treatment was stopped. Ophthalmologically definable scotomata and electroretinographic retinal function changes have also been reported.
BSP Laboratory Studies
Greater than 5% retention of sulfobromophthalein (BSP) has been reported in approximately 10 to 20% of patients in whom it was measured. Retention was usually minimal but was elevated during prolonged clomiphene citrate administration or with apparently unrelated liver disease. In some patients, pre-existing BSP retention decreased even though clomiphene citrate therapy was continued. Other liver function tests were usually normal.
Other Laboratory Studies
Clomiphene citrate has not been reported to cause a significant abnormality in hematologic or renal tests, in protein bound iodine, or in serum cholesterol levels.
Birth Defects
Of 1803 births following clomiphene citrate administration, 45 infants with birth defects were reported for a cumulative rate of 2.5%.
Six cases of Down's Syndrome, one neonatal death with multiple malformations and one case each of the following were reported: extropia, club foot, tibial torsion, blocked tear duct and hemangioma. The other congenital abnormalities were not described. The investigators did not report that these were presumed to be due to therapy. The cumulative rate of congenital abnormalities does not exceed that reported in the general population.

CLINICAL SECTION

Clinical Opinion

Fetal and neonatal cardiovascular complications from β-sympathomimetic therapy for tocolysis 1
Vern L. Katz, MD, and John W. Seeds, MD
Chapel Hill, North Carolina

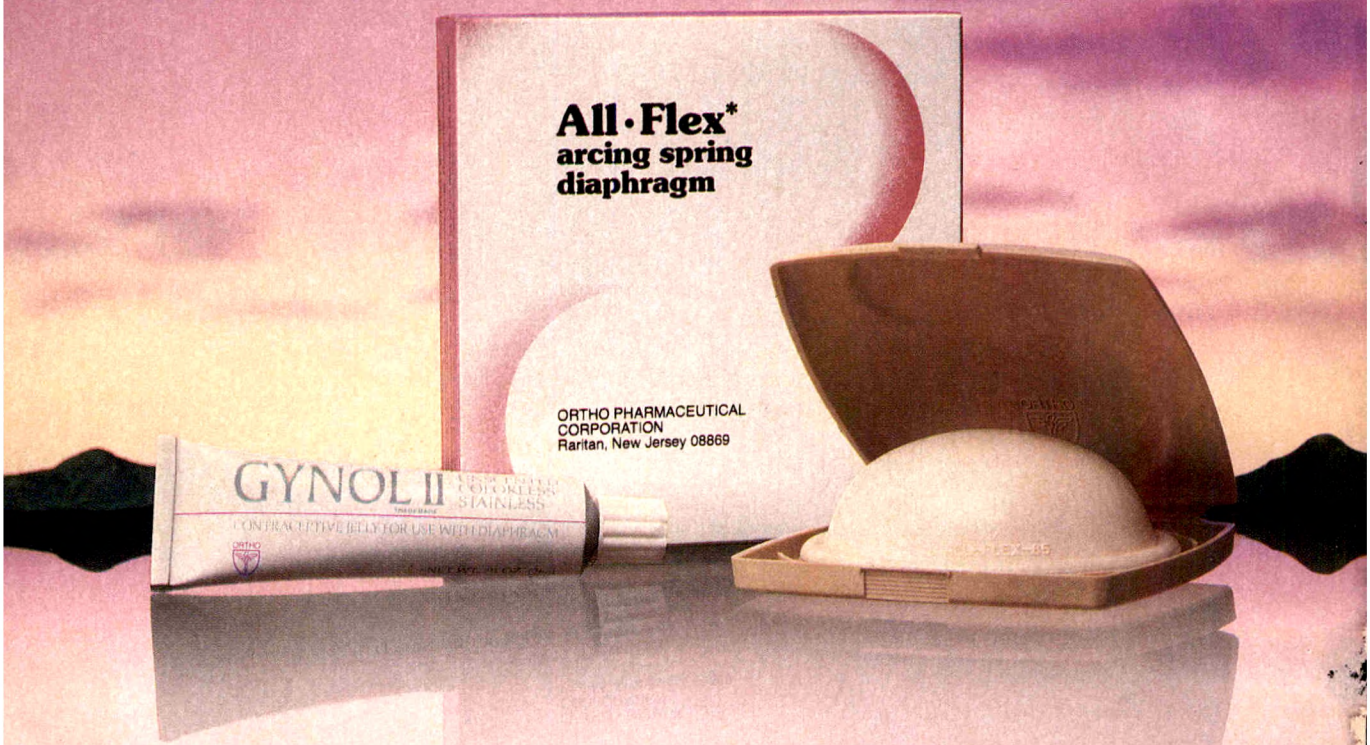
β-Sympathomimetic tocolytic agents have significant fetal cardiac side effects that may occasionally be life-threatening.

Understanding and eliminating errors in perinatal research 5
Barry S. Block, MS, MD
Chicago, Illinois

The valid interpretation of the results and conclusions of experimental studies is encouraged to avoid publication of misleading studies that adversely affect clinical practice.

A case-control study of epithelial ovarian cancer 10
Patricia Hartge, ScD, Mark H. Schiffman, MD, Robert Hoover, MD, Larry McGowan, MD, Linda Lesher, MHS, and Henry J. Norris, MD
Bethesda, Maryland, and Washington, D.C.

Study results confirm the importance of parity, infertility, family history, and previous breast cancer in the etiology of epithelial ovarian cancer.



Heuristic determination of relevant diagnostic procedures in a medical expert system for gynecology 17
Steven L. Small, PhD, and Eberhard K. Muechler, MD
Pittsburgh, Pennsylvania, and Rochester, New York

We describe a medical expert system for problem solving in the gynecologic domain of infertility.

Vol. 161, No. 1, July 1989. The American Journal of Obstetrics and Gynecology (ISSN 0002-9378) is published monthly (six issues per volume, two volumes per year) by The C.V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318. Second-class postage paid at St. Louis, Missouri, and additional mailing offices. POSTMASTER: Send address changes to The C.V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318, (314) 872-8370, ext. 351. Annual subscription rates for 1989: domestic, $65.50 for individuals and $118.00 for institutions. Printed in the U.S.A. Copyright © 1989 by The C.V. Mosby Company.

Satisfaction realized:

87% patient continuation rate† with Ortho ALL-FLEX* Arcing Spring Diaphragm.

Easy for patient to insert—
the Ortho ALL-FLEX* Diaphragm folds easily.

Easy for patient to correctly position in vagina—
the Ortho ALL-FLEX* Diaphragm can be compressed at any two opposing points around the rim.

Easy to use with **GYNOL II* (2% nonoxynol-9) Contraceptive Jelly**—
greaseless, odorless spermicide.

Easy to clean—one-step molding process eliminates gap between spring and dome so jelly or secretions can't accumulate.

Ortho ALL-FLEX*
DIAPHRAGM

†Percentage of patients continuing the method for 12 consecutive months.

Consult the revised patient brochure for new information on Toxic Shock Syndrome (TSS) and wearing time.

Clinical Articles

Breech presentation after cesarean section: Always a section? 25
Ella Ophir, MD, Moshe Oettinger, MD, Arie Yagoda, MD, Yacov Markovits, MD, Nathan Rojansky, MD, and Harry Shapiro, MD
Nahariya, Israel

A trial of labor seems reasonable in carefully selected cases of breech presentation after a previous cesarean section.

Vaginal birth after cesarean delivery in the twin gestation 29
Thomas H. Strong, Jr., MD, Jeffrey P. Phelan, MD, Myoung Ock Ahn, MD, MPH, and Albert P. Sarno, Jr., MD, Maj., USA
Los Angeles, California

No significant increase in morbidity or mortality was noted among women with prior cesarean deliveries who attempted a trial of labor with twins.

Pharmacokinetics of orally administered ritodrine 32
Steven N. Caritis, MD, Raman Venkataramanan, PhD, Margaret Cotroneo, RN, and Jye-Ping Chiao, MS
Pittsburgh, Pennsylvania

Analysis of ritodrine concentration data after oral administration to pregnant subjects indicates that plasma concentrations are low and are unlikely to prevent recurrent preterm labor.

Neuromuscular blockade with magnesium sulfate and nifedipine 35
Scott W. Snyder, MD, and Michael S. Cardwell, MD
Columbia, Missouri

Neuromuscular blockade and respiratory distress occurred in a patient who received a small dose of magnesium after tocolysis with nifedipine.

Usefulness of continuous fetal heart rate monitoring during cesarean section 36
Boris M. Petrikovsky, MD, PhD, Mario Cohen, MD, and M. Leon Tancer, MD
Brooklyn, New York, and Farmington, Connecticut

Two cases in which continuous fetal heart rate monitoring during cesarean section modified the obstetric management are presented.

Risk factors for vulvar lichen sclerosus 38
Mario Sideri, MD, Fabio Parazzini, MD, Maria Teresa Rognoni, MD, Carlo La Vecchia, MD, Eva Negri, ScD, Salvatore Garsia, MD, Elena Arnoletti, MD, and Gabriela Cecchetti, MD
Milan, Italy, and Lausanne, Switzerland

The risk factors for vulvar lichen sclerosus have been assessed in a case-control study; the risk increased with increasing parity and decreasing intake of retinoid, but no relation emerged with menopausal status, socioeconomic indicators, smoking, and sexual habits.

Fetal liver length in normal and isoimmunized pregnancies 42
Alistair B. Roberts, MD, Jennifer M. Mitchell, and Neil S. Pattison, MD
Auckland, New Zealand

Ultrasonographic assessment of fetal liver length measurements correlates well with fetal hemoglobin levels in isoimmunized pregnancies.

Does midtrimester ΔOD_{450} of amniotic fluid reflect severity of Rh disease? 47
Uma Ananth, MD, And John T. Queenan, MD
Washington, D.C.

Second-trimester elevated amniotic fluid delta optical densities indicate severely affected fetuses.

Increased frequency of detection of human papillomavirus deoxyribonucleic acid in exfoliated cervical cells during pregnancy 50
Robert F. Rando, PhD, Steven Lindheim, MD, Lisa Hasty, MD, Thomas V. Sedlacek, MD, Mark Woodland, MD, and Catherine Eder, BA
Philadelphia, Pennsylvania

Detectable levels of HPV DNA in exfoliated cervical cells increased dramatically during pregnancy and a natural fluctuation in the detectable levels of HPV was observed over time.

Contents

Mechanism for human papillomavirus transmission at birth 55
Thomas V. Sedlacek, MD, Steven Lindheim, MD, Catherine Eder, BA, Lisa Hasty, MD, Mark Woodland, MD, Avi Ludomirsky, MD, and Robert F. Rando, PhD
Philadelphia, Pennsylvania

HPV DNA was detected in the nasopharyngeal cavity of neonates.

A ten-year experience treating cervical intraepithelial neoplasia with the CO_2 laser 60
Michael S. Baggish, MD, James H. Dorsey, MD, and Mark Adelson, MD
Syracuse, New York, and Baltimore, Maryland

Cure rates for cervical intraepithelial neoplasia between 94% and 97% were obtained in 4024 women treated with the CO_2 laser.

Anal submucosal injection: A new route for drug administration in pelvic malignancies. IV. Submucosal anal injection in the treatment of cancer of uterine cervix—Preliminary study 69
Ahmed Shafik, MD
Cairo, Egypt

Seven patients with advanced cancer of the uterine cervix, treated by anal submucosal injection of methotrexate, showed complete response with no side effects.

Aggressive angiomyxoma first diagnosed as levator hernia 73
Gregory P. Sutton, MD, Robert E. Rogers, MD, Lawrence M. Roth, MD, and Clarence E. Ehrlich, MD
Indianapolis, Indiana

Physical findings of an aggressive angiomyxoma first suggested a levator hernia; computed tomography aided in the diagnosis and excision.

Asymptomatic thrombocytopenia associated with chorioangioma of placenta 76
Nirmala S. Limaye, MD, and Jean-Gilles Tchabo, MD
Arlington, Virginia

A case of chorioangioma is presented.

First-trimester and early second-trimester diagnosis of nuchal cystic hygroma by transvaginal sonography: Diverse prognosis of the septated from the nonseptated lesion 78
M. Bronshtein, MD, S. Rottem, MD, N. Yoffe, MD, and Z. Blumenfeld, MD
Haifa, Israel

Half of eight cases of nuchal cystic hygroma were nonseptated and normal fetuses resulted; the other four cases had septated lesions and ended in fetal death or were associated with aneuploidy.

Contents continued from page 9A

Enlarged cisterna magna in trisomy 18: Prenatal ultrasonographic diagnosis 83
Amy S. Thurmond, MD, David W. Nelson, MD, Richard I. Lowensohn, MD, William P. Young, MD, and Lowell Davis, MD
Portland, Oregon

Ultrasonographic visualization of an enlarged cisterna magna was the initial clue that led to the prenatal diagnosis of trisomy 18 in five patients.

Neonatal mortality in normal birth weight babies: Does the level of hospital care make a difference? 86
Cynthia J. Berg, MD, Charlotte M. Druschel, MD, MPH, Brian J. McCarthy, MD, Michael LaVoie, and R. Louise Floyd, RN, MSN
Atlanta, Georgia

Women with high prepartum risk scores who were delivered of normal birth weight infants had a lower neonatal mortality rate if delivery occurred in a level 2 or 3 hospital.

Postdate fetal surveillance: Is 41 weeks too early? 91
Denise A. Guidetti, MD, Michael Y. Divon, MD, and Oded Langer, MD
Bronx, New York

The abnormal fetal testing and adverse perinatal outcome associated with pregnancies >42 weeks were also found in pregnancies between 41 and 42 weeks' gestation.

Sarcoma associated with pregnancy 94
Yutaka Kyodo, MD, Kenji Inatomi, MD, and Tadayuki Abe, MD
Shizuoka, Japan

Sarcoma associated with pregnancy is reported; the patient underwent a cesarean section with myomectomy.

Primary stress urinary incontinence and pelvic relaxation: Prospective randomized comparison of three different operations 97
Arieh Bergman, MD, Paul P. Koonings, MD, and Charles A. Ballard, MD
Los Angeles, California

The Burch urethropexy resulted in a better cure rate in women with pelvic relaxation and stress urinary incontinence than did the Pereyra procedure or anterior colporrhaphy.

Saline solution amnioinfusion for oligohydramnios after premature rupture of the membranes 102
Motoharu Imanaka, MD, Sachio Ogita, MD, and Tadashi Sugawa, MD
Osaka, Japan

Saline solution that contained antibiotics was infused directly into the amniotic cavity by means of a new cervical catheter to successfully treat oligohydramnios after premature rupture of the membranes.

Contents

Prematurity among insulin-requiring diabetic gravid women 106
Michael F. Greene, MD, John W. Hare, MD, Martha Krache, RN, MPH, Mark Phillippe, MD, Vanessa A. Barss, MD, Daniel H. Saltzman, MD, Allan Nadel, MD, M. Donna Younger, MD, Linda Heffner, MD, PhD, and J. Elizabeth Scherl, MD
Boston, Massachusetts

Hypertension was the single most important immediate cause of and risk factor for premature delivery among 420 diabetic gravid women.

Management of the nonvertex second twin: Primary cesarean section, external version, or primary breech extraction 111
Stephen E. Gocke, MD, Michael P. Nageotte, MD, Thomas Garite, MD, Craig V. Towers, MD, and Wendy Dorcester, PhD
Fresno and Long Beach, California

Similar neonatal outcomes were seen when nonvertex second twins were delivered by cesarean section, external version, or breech extraction; however, intrapartum complications were more common when external version was attempted.

Magnesium supplementation during pregnancy: A double-blind randomized controlled clinical trial 115
Baha M. Sibai, MD, Marco A. Villar L., MD, and Eileen Bray, RNC
Memphis, Tennessee

Magnesium supplementation during pregnancy starting at 13 to 26 weeks' gestation did not reduce the incidence of either preeclampsia or fetal growth retardation.

Methicillin-resistant staphylococcal mastitis 120
Charles Kalstone, MD
Miami, Florida

Postpartum mastitis that does not respond to standard antibiotic therapy may require oral trimethoprim and sulfamethoxazole (Bactrim, Septra) or intravenous vancomycin for methicillin-resistant staphylococci.

Gestational trophoblastic disease: A case-control study from the People's Republic of China 121
Louise A. Brinton, PhD, Bao-Zhen Wu, MD, Wen Wang, MD, Abby G. Ershow, ScD, Hong-Zhao Song, MD, Jun-Yao Li, MD, Michael B. Bracken, PhD, and William J. Blot, PhD
Bethesda, Maryland, Beijing, People's Republic of China, and New Haven, Connecticut

A case-control study in the People's Republic of China of 331 patients with complete hydatidiform mole and 662 community controls showed reduced risks associated with a prior term birth or a history of infertility and increased risks with prior induced abortions, use of herbal medicines during pregnancy, and extended durations of oral contraceptive use.

Randomized treatment of mucopurulent cervicitis with doxycycline or amoxicillin 128
Jorma Paavonen, MD, Pacita L. Roberts, MS, Claire E. Stevens, MA, PA, Pål Wølner-Hanssen, MD, Robert C. Brunham, MD, Sharon Hillier, PhD, Walter E. Stamm, MD, Cho-Chou Kuo, MD, Timothy DeRouen, PhD, King K. Holmes, MD, PhD, and David A. Eschenbach, MD
Seattle, Washington

Doxycycline and amoxicillin effectively treated chlamydial and nonchlamydial cervicitis, as assessed by clinical and microbiologic criteria.

Right ventricular dysfunction in human fetal compromise 136
Juha Räsänen, MD, Pertti Kirkinen, MD, and Pentti Jouppila, MD
Oulu, Finland

Fetal M-mode echocardiography demonstrated decreased right ventricular fractional shortening and increased right/left ratio of ventricular inner end-diastolic diameters in fetuses with severe intrauterine distress.

Preterm and term fetal cardiac and movement responses to vibratory acoustic stimulation 141
Ronald L. Thomas, MD, Timothy R. B. Johnson, MD, Richard E. Besinger, MD, Deedra Rafkin, RN, Catharine Treanor, RN, and Donna Strobino, PhD
Baltimore, Maryland

High occurrence of increased baseline, tachycardia, and unusual fetal heart rate patterns accompanies use of vibratory acoustic stimulation.

Effect of physician characteristics on the cesarean birth rate 146
Gertrud S. Berkowitz, PhD, Gale S. Fiarman, MD, Michael A. Mojica, MD, Jay Bauman, MD, and Roberta Haynes de Regt, MD
New York and Elmhurst, New York

Physician characteristics may affect the indications for which cesarean sections are performed.

Court-ordered cesarean section: An analysis of ethical concerns in compelling cases 150
Thomas E. Elkins, MD, H. Frank Andersen, MD, Mel Barclay, MD, Tina Mason, MD, Noelle Bowdler, MD, and Garland Anderson, MD
Ann Arbor, Michigan, and Memphis, Tennessee

A discussion is presented of the ethical concerns that arise when a court order is sought to perform a cesarean section.

Removing a retained placenta by oxytocin—A controlled study 155
Charlotte Wilken-Jensen, MD, Verner Strøm, MD, Meta Damkjær Nielsen, MSc, and Bo Rosenkilde-Gram, MD
Gentofte, Denmark

Retained placenta can successfully and safely be treated with injection of 100 IU of oxytocin into an umbilical vein.

Contents

The use of transvaginal ultrasonography in the diagnosis of ectopic pregnancy 157
Ilan E. Timor-Tritsch, MD, Ming N. Yeh, MD, David B. Peisner, MD, Karen B. Lesser, MD, and Theresa A. Slavik, BA, RDMS
New York, New York

High-frequency transvaginal ultrasonography proved to be effective in the workup of the patient with suspected ectopic pregnancy.

Ileocecal vaginal construction 162
Rainer A. Bürger, MD, Hubertus Riedmiller, MD, Paul G. Knapstein, MD, Volker Friedberg, MD, and Rudolf Hohenfellner, MD
Mainz, West Germany

Indications for ileocecal and cecal vaginoplasty with detailed descriptions of operative and vaginal replacement techniques are reviewed and discussed.

Renal artery flow-velocity waveforms in normal and hypoxemic fetuses 168
S. Vyas, MD, K. H. Nicolaides, MD, and S. Campbell, MD
London, England

The fetal renal artery was identified by color flow mapping, and a reference range of the pulsatility index with gestation was established; subsequently, 18 SGA fetuses were examined and a significant correlation found between degree of fetal hypoxemia and increase in renal artery pulsatility index.

Twin pregnancy in premature ovarian failure after estrogen treatment: A case report 172
Lawrence Tang, MD, and Robert S. Sawers, MD
Birmingham, England

A patient with premature ovarian failure was given estrogen treatment that unexpectedly induced superovulation, resulting in a dizygotic twin pregnancy.

Uterine development and endocrine relationships after menarche 174
Eleonora Porcu, MD, Stefano Venturoli, MD, Raffaella Fabbri, BSc, Luigi F. Orsini, MD, Emilia Sganga, MD, Lorena Brondelli, MD, Roberto Paradisi, MD, and Carlo Flamigni, MD
Bologna, Italy

The uterus continues to grow after menarche.

Leiomyoma of the ovary with ascites and hydrothorax 177
Jonathan J. Nicoll, MA, and Peter J. Cox, MS
London, England

We describe a case in which leiomyoma of the ovary occurred with ascites and hydrothorax.

(Contents continued on page 14A)

Contents continued from page 13A

Individual growth curve standards in twins: Prediction of third-trimester growth and birth characteristics 179
Theodor Stefos, MD, Russell L. Deter, MD, Reba M. Hill, MD, and Nicolas V. Simon, MD
Houston, Texas, and York, Pennsylvania

Rossavik growth models for five anatomic parameters, derived from second-trimester growth curves, accurately predicted third-trimester growth and birth characteristics in twins, as they do in singletons.

Effect of birth weight, race, and sex on survival of low-birth-weight infants in neonatal intensive care 184
Michael B. Resnick, EdD, Randy L. Carter, PhD, Mario Ariet, PhD, Richard L. Bucciarelli, MD, Janet H. Evans, MSPA, Robert R. Furlough, PhD, William W. Ausbon, MD, and John S. Curran, MD
Gainesville, Tallahassee, and Tampa, Florida

Curves by race and sex illustrate the probability of survival of neonates at any specific birth weight.

Effects of maternal hyperoxia on the biophysical assessment of fetuses with suspected intrauterine growth retardation 188
David A. Ruedrich, MD, Lawrence D. Devoe, MD, and Nancy Searle, BA
Augusta, Georgia

The biophysical effects of maternal hyperoxia may improve the diagnostic accuracy of detecting intrauterine growth retardation.

Fetal radius length: A critical evaluation of race as a factor in gestational age assessment 193
Lyndon M. Hill, MD, David Guzick, MD, PhD, Marion L. Thomas, RT, RDMS, and Joanne K. Fries, RDMS
Pittsburgh, Pennsylvania

Assessment of gestational age from radius length incorporates racial factor.

Pregnancy after aortofemoral bypass grafting in a diabetic patient 200
P. J. Bradley-Watson, FRCS, FRCOG
Dyfed, Wales

A successful pregnancy after aortofemoral bypass grafting in a diabetic patient is described; this is believed to be the first case of its kind to be reported.

Fentanyl citrate analgesia during labor 202
William Rayburn, MD, Anne Rathke, RN, M. Patricia Leuschen, PhD, Jan Chleborad, MD, and William Weidner, MD
Omaha, Nebraska

Intravenous fentanyl citrate, a potent and short-acting narcotic, was helpful during labor without immediate or prolonged hazards to the mother or unborn infant.

Contents

Significance of D-mannose as a sperm receptor site on the zona pellucida in human fertilization 207
Kazumasa Mori, MD, Toshifumi Daitoh, MD, DMSc, Minoru Irahara, MD, DMSc, Masaharu Kamada, MD, DMSc, and Toshihiro Aono, MD, DMSc
Tokushima, Japan

Pretreatments of spermatozoa with D-mannose or of the zona pellucida with concanavalin A completely inhibited sperm penetration through the human zona pellucida.

The importance of ultrasonography in infertile women with "forgotten" intrauterine contraceptive devices 211
Raphael Ron-El, MD, Zvi Weinraub, MD, Rami Langer, MD, Ian Bukovsky, MD, and Eliahu Caspi, MD
Zerifin and Tel Aviv, Israel

Ultrasonography is a reliable method in diagnosis of an in situ "forgotten" intrauterine contraceptive device.

Acid-base status at birth and neurodevelopmental outcome at four and one-half years 213
Jennifer Dennis, DM, Ann Johnson, MD, Lesley Mutch, MD, Patricia Yudkin, MA, and Paul Johnson, MB, ChB
Oxford, England

A study of 230 term infants showed no statistically significant association between acid-base status at birth and any aspect of neurodevelopment at age 4½ years.

BASIC SCIENCE SECTION

The effect of elevated blood glucose on the electroencephalogram and cerebral metabolism during short-term brain ischemia in fetal sheep 221
Conrad R. Chao, MD, A. Roger Hohimer, PhD, and John M. Bissonnette, MD
Portland, Oregon

Elevation of blood glucose before cerebral ischemia prevents the attenuation of electroencephalographic amplitude seen during ischemia at normal blood glucose levels.

Uncoupling of excitation from contraction in uterine smooth muscle in near-term ewes 229
Deborah L. Reid, PhD, Mark C. Hollister, MD, Susan R. Davidson, MD, Terrance M. Phernetton, BS, and John H. G. Rankin, PhD
Madison, Wisconsin

A new method of assessing tocolytic efficacy is described; prostaglandin E_2–induced changes in intrauterine pressure were suppressed by forskolin but the uterine electromyogram was unaffected.

Gestational diabetes in the BHE rat: Influence of dietary fat 234
Juliana M. Bue, BS, Dorothy B. Hausman, PhD, and Carolyn D. Berdanier, PhD
Athens, Georgia

Long- and short-term feeding to BHE rats of a diet similar to that of human beings results in gestational diabetes.

(Contents continued on page 16A)

Contents continued from page 15A

Effect of inhibiting prostaglandin synthesis in pregnant sheep with 4-aminoantipyrine under normothermic and hyperthermic conditions 241
Peter Andrianakis, BSc(Hons.), David W. Walker, PhD, Meredith M. Ralph, PhD, and Geoffrey D. Thorburn, MD
Clayton, Victoria, Australia

The inhibition of prostaglandin synthesis by 4-aminoantipyrine severely compromises fetal well-being during episodes of hyperthermia.

Progesterone antagonist lilopristone: A potent abortifacient in the common marmoset 248
Chander P. Puri, PhD, Rohini K. Patil, BSc, Sanjiv D. Kholkute, PhD, Walter A. G. Elger, MD, and Xavier R. Swamy, BA
Bombay, India, and Berlin, Federal Republic of Germany

Administration of ZK 98.734 around the time of implantation or during early or mid gestation terminates pregnancy in the common marmoset.

CORRESPONDENCE

Fetal death: Diagnosis and management Paul Merlob, MD *Petah Tikva, Israel* 254

Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Prices include shipping. *Payment must accompany all orders and must be in U.S. funds, drawn on a U.S. bank.*

Contact The C.V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318 USA; phone (314) 872-8370, ext. 394. In the U.S., call toll-free: 1-800-325-4177, ext. 394. Please allow six weeks for delivery.

The Journal is abstracted and/or indexed in *Index Medicus, Science Citation Index, Current Contents/Clinical Medicine, Current Contents/Life Sciences, Excerpta Medica,* BRS Colleague, and MEDLINE.

"When breakthrough bleeding happened to me I was scared, and that's why I called my doctor."

She deserves a

better start

TRI·LEVLEN®

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

54%* less breakthrough bleeding† than Ortho-Novum® 7/7/7

Demonstrated in the largest parallel comparative trial of triphasic OCs to date[1]

*Serious as well as minor side effects have been reported with the use of all oral contraceptives. The physician should remain alert to the earliest symptoms of serious disease and discontinue oral contraceptive therapy when appropriate. Please see full prescribing information, a brief summary of which follows.

†100 women randomly assigned to Tri-Levlen® tablets or Ortho-Novum® 7/7/7; 50 women placed on nonhormonal contraception as a control. Evaluations were made at baseline and once a month for 6 months.

One cycle of Tri-Levlen® tablets therapy provides: ethinyl estradiol–30 mcg/day for 6 days, 40 mcg/day for 5 days and 30 mcg/day for 10 days; levonorgestrel–50 mcg/day for 6 days, 75 mcg/day for 5 days and 125 mcg/day for 10 days. One cycle of Ortho-Novum® 7/7/7 therapy provides: ethinyl estradiol–35 mcg/day for 21 days; norethindrone–500 mcg/day for 7 days, 750 mcg/day for 7 days and 1000 mcg/day for 7 days.

Ortho-Novum® is a registered trademark of Ortho Pharmaceutical Corp.

BERLEX™ Dedicated to innovation in OB/GYN medicine

TRI-LEVLEN® 28 Levonorgestrel and ethinyl estradiol
TRI-LEVLEN® 21 tablets–Triphasic regimen

BRIEF SUMMARY

Tri-Levlen®—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxy-gon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage—Tri-Levlen Tablets are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

Thromboembolic Disorders and Other Vascular Problems: An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 1 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, or to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thrombophlebitis and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to-six-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and other study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.

Ocular Lesions: There have been reports of neuro-ocular lesions, such as optic neuritis or retinal thrombosis, associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

Carcinoma: Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of endometrial carcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for endometrial carcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.

Hepatic Tumors: Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.

Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring: The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been known that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a rare form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are biologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be assumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses in women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. It is recommended that, for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. In one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, increased risk was apparent between 6 and 12 months of use.

7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage of patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase in triglycerides and total phospholipids has been observed in patients receiving OCs. Three studies have been performed with the Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets Triphasic Regimen) formulation and no significant alterations in lipid metabolism were noted, with the exception of a slight increase in triglyceride levels in one study. The clinical significance of the findings remains to be defined.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertension may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to normal after discontinuing the drug.

9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of OCs and evaluation of the cause.

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. Breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. Undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea in young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should be deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical examination and PAP smear being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine and liver-function tests and blood components may be affected by estrogen-containing OCs: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3, increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis—See "Warnings" section for information on the carcinogenic potential of OCs.

Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."

Nursing Mothers—See "Warnings."

Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (see "Warnings"): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.

There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement and secretion; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—To achieve maximum contraceptive effectiveness, Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours. (If Tri-Levlen is first taken later than the first day of the first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of administration. The possibility of ovulation and conception prior to initiation of medication should be considered.) Any time the patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another method of contraception until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information in package insert. 6061I-1 5/86

Specialty: Orthopedic Surgery
AFB: Lackland

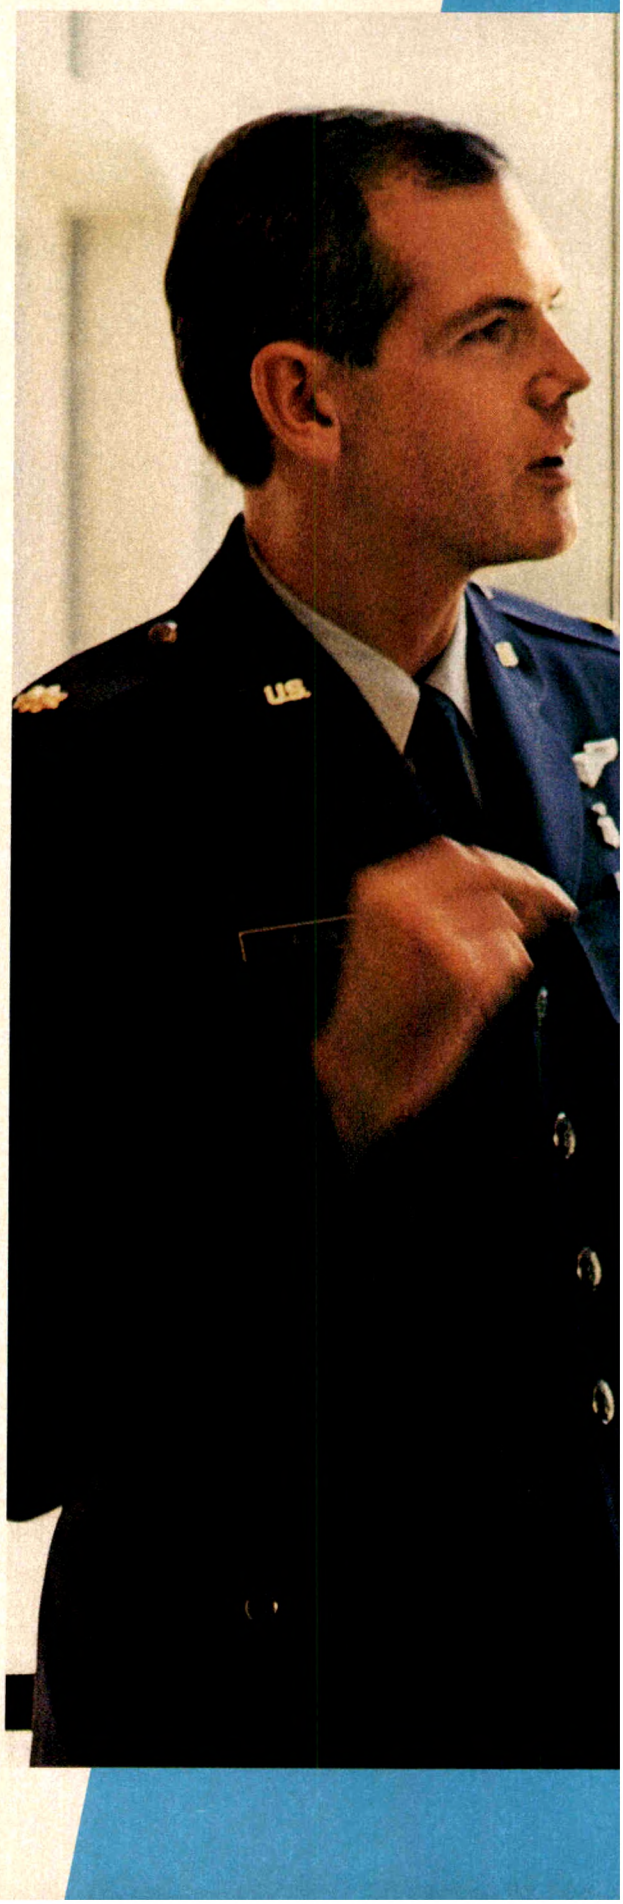
For career and country: Why Dr Mike Wilson became an Air Force physician

"When I finished my residency at the Mayo Clinic, I headed home to Iowa to fulfill my dream of being a community-based orthopedic surgeon. But after several years in which it seemed I spent more time shuffling papers than seeing patients, I realized I was missing the things I wanted from my career in medicine. Helping. Teaching. Learning.

"That's when I investigated the Air Force. I was impressed by what it could offer: The opportunity to see, treat, and follow up on a diverse, interesting population; the academic stimulation of preparing and participating in teaching conferences; the chance to be part of a team that has a clearly defined, vital mission in the world.

"Sure, I don't gross as much as my peers in private practice, but I don't pay out as much, either. Health insurance is not necessary and I earn 30 days of vacation with pay each year; I don't pay a penny for malpractice insurance, staff salaries, or rent. I even receive an untaxed housing allowance, and an excellent, non-contributory pension plan.

"Plus, there's the intangible satisfaction of doing something meaningful for a country that, frankly, has been very good to me.



"For the right person, being an Air Force physician is the best practice in the world. It is for me."

Wilson MD

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1988;108:258-65. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL, and in more detail in the *Guide to Writing for the American Journal of Obstetrics and Gynecology*. The latter may be obtained from The C.V. Mosby Company or the Editors on request.

Manuscript submission. Manuscripts should be submitted to one of the three Editors as follows:

1. **Dr. Brewer**—all manuscripts originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation and The Society of Perinatal Obstetricians.

2. **Dr. Zuspan**—manuscripts from the northeastern quadrant of the United States and from Japan, Israel, Italy, and England, manuscripts written for Clinical Opinion and Current Development, and Letters to the Editors. Dr. Zuspan is responsible for manuscripts from The Society of Perinatal Obstetricians. Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. John A. Read, 9102 Lake Steilacoom Point Road, S.W., Tacoma, WA 98498.

3. **Dr. Quilligan**—manuscripts from the north central states (including Ohio), states west of the Mississippi River, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.

Author's designation of reviewers. When authors submit their manuscripts, they may provide the names and addresses of three reviewers for consideration by the Editors.

Copyright statement. Effective July 1, 1988, all manuscripts must be accompanied by the following written statement, signed by *all* authors: "The undersigned author(s) transfers all copyright ownership of the manuscript [title of article] to The C.V. Mosby Company in the event the work is published. The undersigned author(s) warrants that the article is original; is not under consideration by another publication; and its essential substance, tables, or figures have not been previously published. This restriction does not apply to abstracts or press reports published in connection with scientific meetings. The author(s) confirms the final manuscript has been read and each author's contribution has been approved by the appropriate author. The author(s) responsible for the manuscript must be identified."

Previous publication. If a report by the same author(s) has been previously published in any medium that deals in any respect whatever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. The author(s) should inform the Editor of the circumstances of the two reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and animal experimentation. It is assumed by the Editors that manuscripts emanating from a particular

institution are submitted with the approval of the requisite authority. Human experimentation that requires local institutional approval must have this approval *before the experiment is started* and approval must be so indicated in the Methods section of the submitted manuscript. Reports of experiments on animals must *state in the Methods section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or publisher, and the Editor(s) and publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of glossy prints of illustrations are required.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, and business and home telephone numbers of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, and business and home telephone numbers of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page and key words/phrases. On manuscript page 3 type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors*. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Avoid duplication of text and supporting material. Emphasize only your important observations; do not compare your

Estimating length of manuscripts

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200-word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

observations with those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number are allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (Ann Intern Med 1988;108:258-65). Journal titles should conform to abbreviations used in *Cumulated Index Medicus*.

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Fischermann E, Quilligan EJ, et al. Vaginal delivery following cesarean section—use of oxytocin augmentation and epidural anesthesia. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: James VHT, Folkerd EJ, Bonney RC, Beranek PA, Reed MJ. Factors influencing estrogen production and metabolism in postmenopausal women with endocrine cancer. In: van Herendael HB, Riphagen FE, Goessens L, van der Pas H, eds. The climacteric, an update. Lancaster, England: MTP Press, 1983:29.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. This signed permission must accompany the manuscript when it is submitted to the Editor. Abstracts are not acceptable as numbered references.

Illustrations and tables. Illustrations and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice.

A reasonable number of halftone and line illustrations will be reproduced without charge, but special arrangements must be made with the Editors for *color illustrations* at a cost of $525 per page (one side).

For *color photographs* submit original transparencies and two sets of unmounted prints on glossy (smooth-surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The *top, first author's last name,* and *figure number* must be indicated on the front of each transparency and the back of each print. Consistency in size of illustrations within the article is strongly preferred.

For *black-and-white illustrations* submit three sets of 3 × 4 inch (minimum) to 5 × 7 inch (maximum) unmounted, glossy photographic prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints with good black-and-white contrast. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted.

Do not use paper clips or mar the surface of prints in any way.

Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with): author(s) name(s), title of article, number, and top marked clearly.

Figures will be returned only on request by the author.

Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. *If a table or any part thereof has been taken from copyrighted material, a legend to the table must give full credit to the original source.* Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Legends to illustrations. Legends for all figures must be typed double-spaced on paper separate from the text of the manuscript, and these pages must be numbered in sequence after the references. Titles should be included in

the legend, *not* on the print. Original magnifications should be provided. *If an illustration has been taken from copyrighted material, the legend must give full credit to the original source.*

Computer-generated illustrations. *Black-and-white illustrations* submitted must be legible and clearly printed in jet-black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend for the illustration should not appear on the print. On the back of each print the name of the first author and the figure number should be given and the top indicated. Original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color illustrations* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color illustrations. The preparation and submitting of color prints should follow the preceding guidelines for black-and-white computer-generated illustrations.

Permissions. Direct quotations, tables, or illustrations that have appeared in copyrighted material must be accompanied by *written permission* for their use from the copyright owner and original author along with complete information as to source. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article.

Clinical Opinion. Limit of 3000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Correspondence. Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication. All letters should be typed double-spaced. The original and a good photocopy must be submitted. Letters should be sent to Dr. Zuspan.

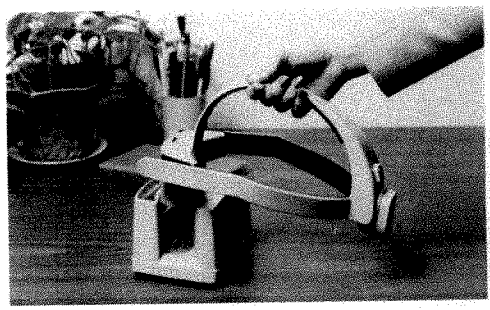
Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, The C.V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.

Reprints

Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the publisher with the author's consent.

Business communications

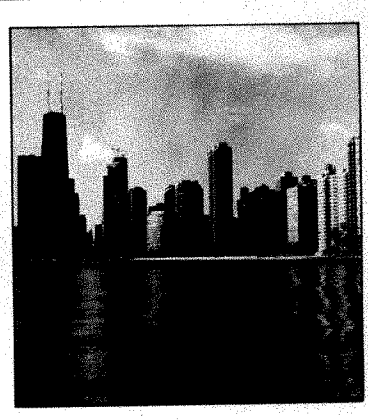


Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, The C.V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (314) 872-8370.

Checklist

—Letter of submission
—Copyright transfer letter
—Copies of other manuscripts containing duplicated data (see paragraph "Previous Publication")
—Original and two photocopies of manuscript
—Title page
  —Title of article
  —Full name(s), highest academic degree(s), and affiliations of author(s)
  —Line citing financial support
  —Author to whom correspondence is to be sent, including address and business and home telephone numbers
  —Reprint requests line or line stating reprints not available
  —Short title
—Condensation (double-spaced)
—Abstract (double-spaced), 3 to 5 key words/phrases
—Article proper (double-spaced)
—References (double-spaced), on a separate sheet
—Legends (double-spaced), on a separate sheet
—Tables (double-spaced), on a separate sheet
— Illustrations, properly labeled (three sets of glossy prints)
—Permission to reproduce published material
—Informed consent for patient photographs

TIRED OF BEING TIED DOWN?
Introducing
THE RIGHT LIGHT™



FINALLY, an examination light that allows you the freedom you wanted. There are no restrictive cords tying you to an electrical outlet. Both hands are free. Developed through the efforts of a physician team and an electrical engineer, THE RIGHT LIGHT™ answers the need for a reliable, cordless, lightweight head-mounted illuminator.

- Portable (No umbilical cord)
- Rechargeable
- High intensity halogen beam
- High capacity powerpack
- Easily adjusted headband
- Light lowers from headband for optimum line-of-sight illumination
- Swivel directed light beam
- Desk or wall-mounted charger
- Charger UL listed
- Recharges overnight
- Charging indicator
- Lasts 2 hours per charge
- ON-OFF switch to conserve energy

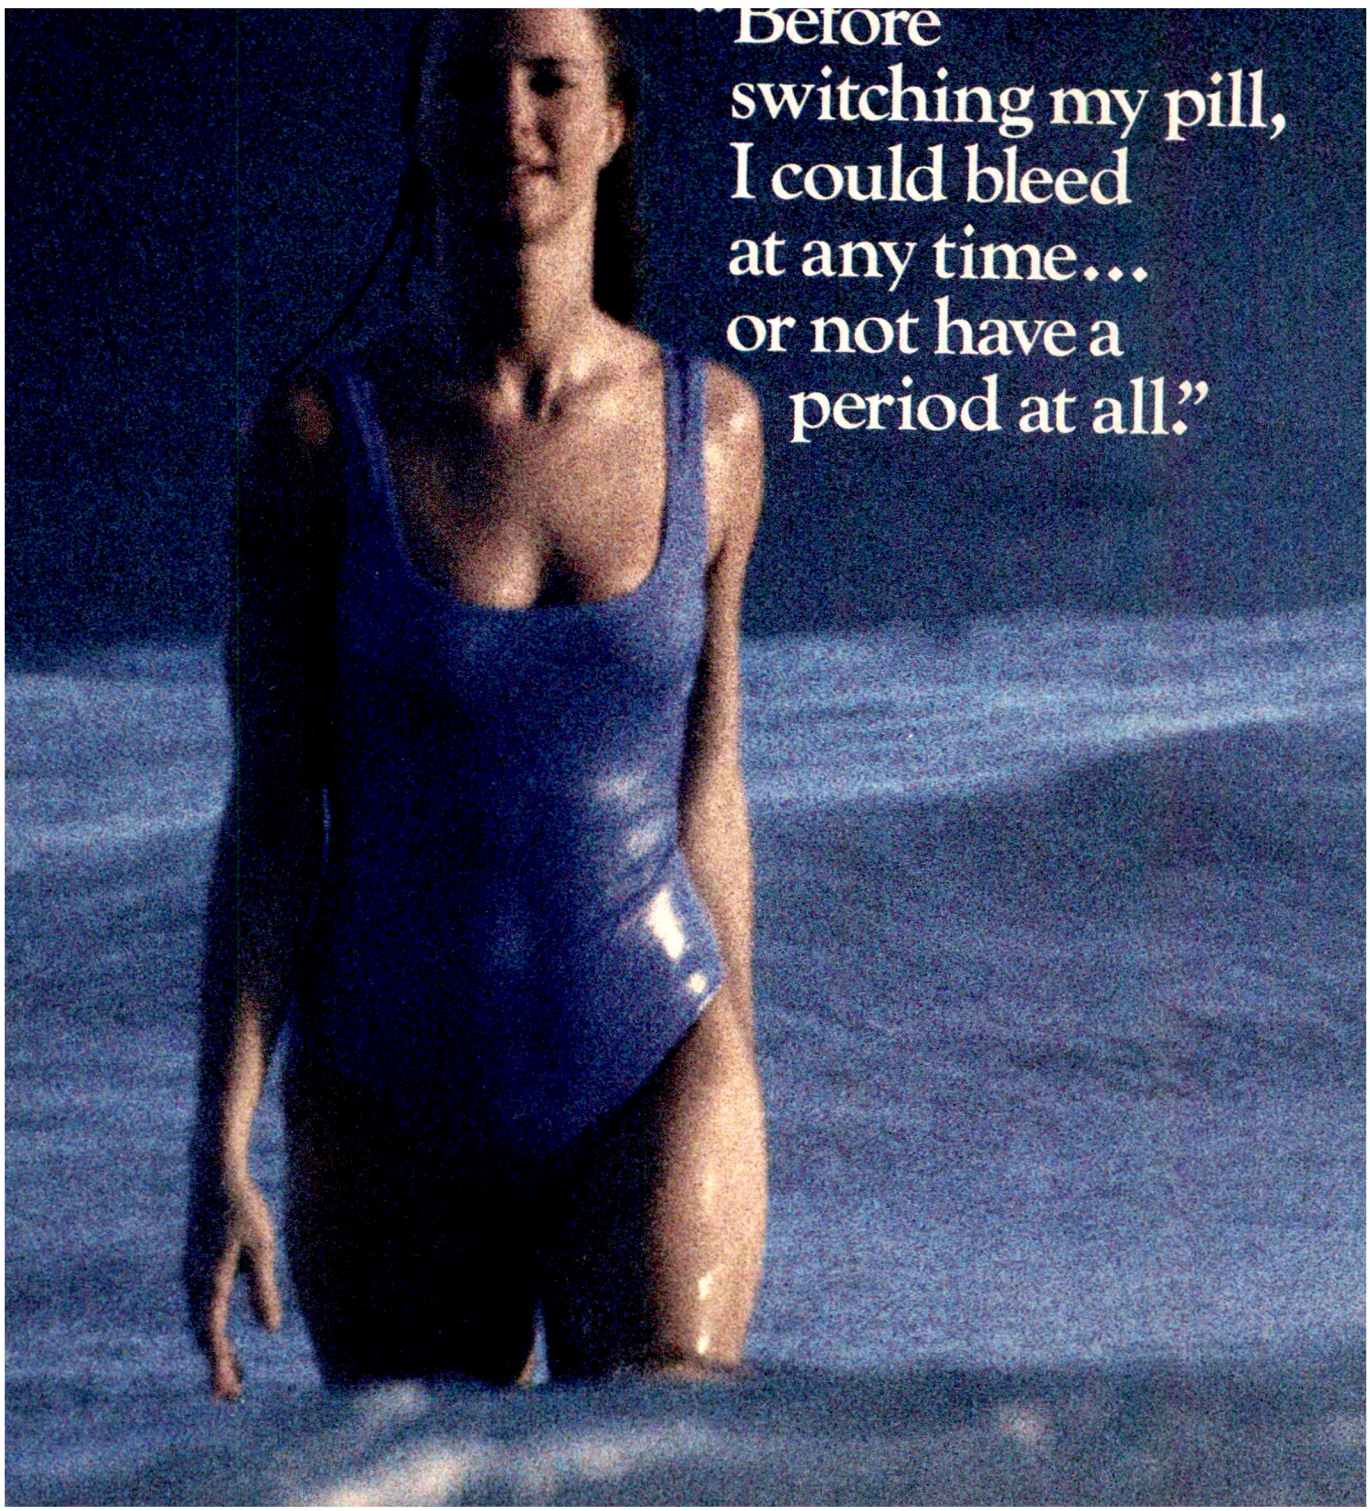
IdenTechs

To order your RIGHT LIGHT™ call 1-800-545-6775. In Illinois 312-690-0177. The price of $220.00 includes tax, shipping and handling. Visa and MasterCard charge accepted. If you prefer to order by mail send a check or money order to IdenTechs, P.O. Box 524, Wheaton, Illinois 60187.

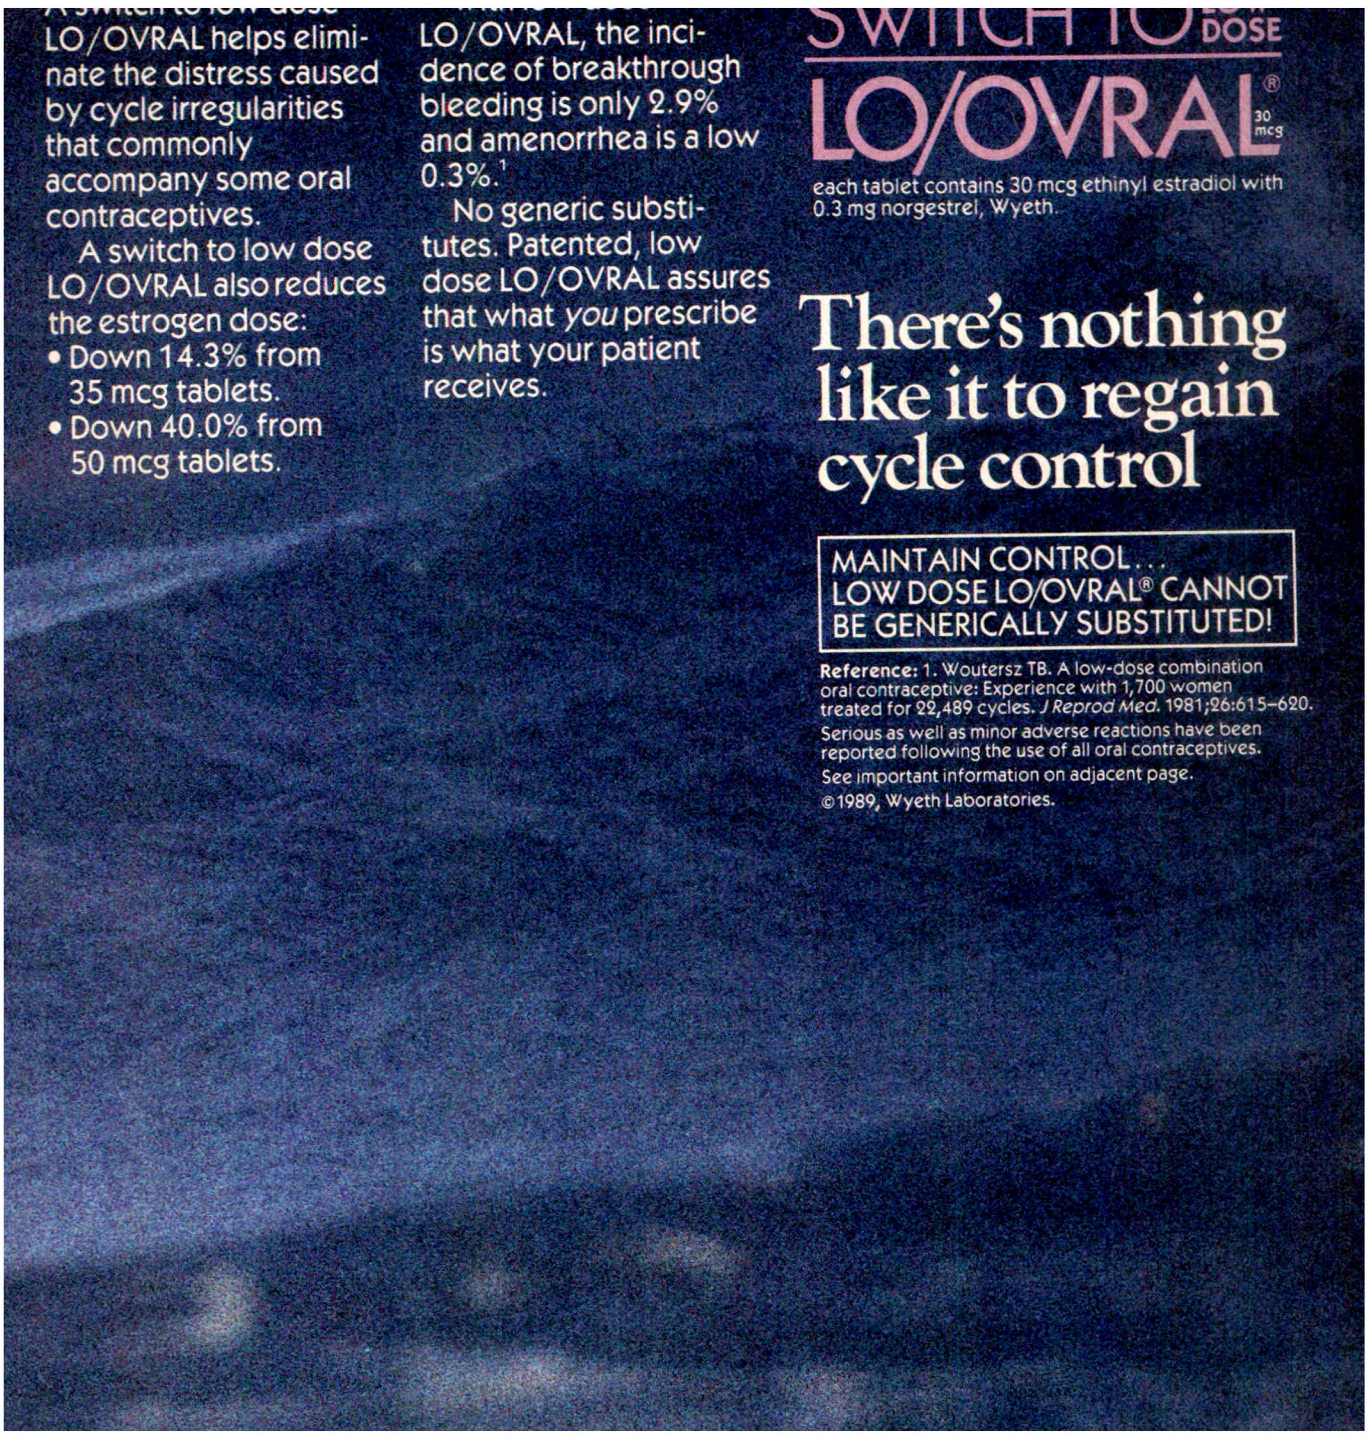
Specialty Review in Obstetrics and Gynecology: Practical Aspects

October 15 – 21, 1989

• Chicago •



Course Coordinator: M. LeRoy Sprang, M.D., Assistant Professor of Clinical Obstetrics and Gynecology, Northwestern University Medical School, Chicago



For those who seek a review of all aspects of Obstetric and Gynecologic practice. Particular emphasis is placed on the state of the art in diagnosis and management and contemporary solutions to common dilemmas. Lectures are presented by leading clinicians who are also known for their effective teaching skills. Two special features are an **Optional Microscope Slide Review,** offering you a unique opportunity for tutelage in pathologic identification; and a **Review of Case Lists,** affording the chance to review your cases with a panel of experts.

Participation earns **53 AMA Category 1 credit hours.** Application has been made for cognates from the American College of Obstetricians and Gynecologists.

THE COOK COUNTY GRADUATE SCHOOL OF MEDICINE
CME Since 1932

"Before
switching my pill,
I could bleed
at any time...
or not have a
period at all."

LO/OVRAL helps eliminate the distress caused by cycle irregularities that commonly accompany some oral contraceptives.
A switch to low dose LO/OVRAL also reduces the estrogen dose:
• Down 14.3% from 35 mcg tablets.
• Down 40.0% from 50 mcg tablets.
LO/OVRAL, the incidence of breakthrough bleeding is only 2.9% and amenorrhea is a low 0.3%.[1]
No generic substitutes. Patented, low dose LO/OVRAL assures that what *you* prescribe is what your patient receives.
SWITCH TO DOSE
LO/OVRAL® 30 mcg
each tablet contains 30 mcg ethinyl estradiol with 0.3 mg norgestrel, Wyeth.
There's nothing like it to regain cycle control
MAINTAIN CONTROL . . .
LOW DOSE LO/OVRAL® CANNOT BE GENERICALLY SUBSTITUTED!
Reference: 1. Woutersz TB. A low-dose combination oral contraceptive: Experience with 1,700 women treated for 22,489 cycles. *J Reprod Med.* 1981;26:615–620.
Serious as well as minor adverse reactions have been reported following the use of all oral contraceptives.
See important information on adjacent page.
©1989, Wyeth Laboratories.

IN BRIEF:

Indications and Usage—LO/OVRAL® is indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OC's) as a method of contraception.

Contraindications—OC's should not be used in women with any of the following conditions:

1. Thrombophlebitis or thromboembolic disorders.
2. A past history of deep-vein thrombophlebitis or thromboembolic disorders.
3. Cerebral-vascular or coronary-artery disease.
4. Known or suspected carcinoma of the breast.
5. Known or suspected estrogen-dependent neoplasia.
6. Undiagnosed abnormal genital bleeding.
7. Known or suspected pregnancy (see Warning No. 5).
8. Benign or malignant liver tumor which developed during use of OC's or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems*—An increased risk of thromboembolic and thrombotic disease associated with use of OC's is well established. Three principal studies in Great Britain and 3 in the U.S. have demonstrated increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OC's are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION (MI)—An increased risk of MI associated with use of OC's has been reported, confirming a previously suspected association. These studies, conducted in the UK, found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia) the higher the risk of developing MI, regardless of whether the patient was an OC user or not. OC's, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to MI) are about twice as likely to have a fatal MI as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal MI compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, amount of smoking is also an important factor. In determining importance of these relative risks, however, baseline rates for various age groups must be given serious consideration. Importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; quite likely the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse-reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to dose of estrogen in OC's. Preparations containing 100 mcg or more of estrogen were associated with higher risk of thromboembolism than those containing 50-80 mcg. Their analysis did suggest, however, that quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the U.S.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the UK estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OC's according to age, smoking habits, and duration of use. Overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), risk being concentrated in older women, in those with long duration of use, and in cigarette smokers. It was not possible, however, to examine interrelationships of age, smoking, and duration of use, nor to compare effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess magnitude of relative risk for this younger group. Available data from a variety of sources have been analyzed to estimate risk of death associated with various methods of contraception. Estimates of risk of death for each method include combined risk of contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OC's) plus risk attributable to pregnancy or abortion in event of method failure. This latter risk varies with effectiveness of method. The study concluded that mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OC's in women over 40 who smoke. Lowest mortality is associated with condom or diaphragm backed up by early abortion. Risk of thromboembolic and thrombotic disease associated with OC's increases with age after about 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of pre-eclamptic toxemia, and especially cigarette smoking. Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A 4- to 6-fold increased risk of postsurgery thromboembolic complications has been reported in OC users.

If feasible, OC's should be discontinued at least 4 weeks before surgery of a type associated with increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Britain involving cerebrovascular disease and another in the U.S. concerning MI suggest an increased risk of these conditions in users of OC's persists after discontinuation of the OC's. In the British study, risk of cerebrovascular disease remained elevated in former OC users for at least 6 years after discontinuation. In the U.S. study, increased risk of MI persisted for at least 9 years in women 40- to 49-years-old who had used OC's for 5 or more years. Findings in both studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions*—There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with use of OC's. Discontinue OC's if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma*—Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in OC's, have been noted to increase incidence of mammary nodules, benign and malignant, in dogs. In humans, 3 case-control studies have reported an increased risk of endometrial carcinoma associated with prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OC's. Of cases found in women without predisposing risk factors (e.g., irregular bleeding at the time OC's were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These are no longer marketed. No evidence has been reported suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only OC's. Several studies have found no increase in breast cancer in women taking OC's or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women on OC's, found an excess risk in subgroups of OC users with documented benign breast disease. Reduced occurrence of benign breast tumors in users of OC's has been well documented. In summary, there is at present no confirmed evidence from human studies of increased risk of cancer associated with OC's. Close clinical surveillance of all women on OC's is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms should be monitored with particular care if they elect to use OC's.

4. *Hepatic Tumors*—Benign hepatic adenomas have been found to be associated with use of OC's. One study showed that OC's with high hormonal potency were associated with higher risk than lower potency OC's. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users. Two studies relate risk with duration of use of OC's, the risk being much greater after 4 or more years' use. While hepatic adenoma is rare, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women on OC's. Relationship of these drugs to this type of malignancy is not known.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring*—Use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have increased risk of developing in later life a form of vaginal or cervical cancer ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence now that OC's further enhance risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OC's. Furthermore, 30 to 90% of such exposed women have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with use of other estrogens, it cannot be presumed they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with use of sex hormones, including OC's, in pregnancy. One case control study estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OC's, hormonal withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some exposures involved only a few days. Data suggest that risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OC's. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OC's is unknown. It is recommended that, for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing OC's. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at time of first missed period, and further use of OC's should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and advisability of continuation of the pregnancy should be discussed. It is also recommended that women who discontinue OC's with intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this. The administration of progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease*—Studies report increased risk of surgically confirmed gallbladder disease in users of OC's and estrogens. In one study, increased risk appeared after 2 years' use and doubled after 4 or 5 years' use. In one of the other studies, increased risk was apparent between 6 and 12 months' use.

7. *Carbohydrate and Lipid Metabolic Effects*—Decrease in glucose tolerance has been observed in a significant percentage of patients on OC's. For this reason, prediabetic and diabetic patients should be carefully observed while on OC's. Increase in triglycerides and total phospholipids has been observed in patients on OC's; clinical significance of this finding remains to be defined.

8. *Elevated Blood Pressure*—Increase in blood pressure has been reported in patients on OC's. In some women, hypertension may occur within a few months of beginning OC's. In the 1st year of use, prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. Prevalence in users increases, however, with longer exposure, and in the 5th year of use is 2½ to 3 times the reported prevalence in the 1st year. Age is also strongly correlated with development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure on OC's. Hypertension that develops as a result of taking OC's usually returns to normal after discontinuing the drug.

9. *Headache*—Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of OC's and evaluation of the cause.

10. *Bleeding Irregularities*—Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing OC's. In breakthrough bleeding, as in all cases of irregular vaginal bleeding, nonfunctional causes should be borne in mind.

In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another OC may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase risk of thromboembolic disease. Women with past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuing OC's. Women with these pre-existing problems should be advised of this possibility and encouraged to use other methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy*—Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding*—OC's given in the postpartum period may interfere with lactation and decrease quantity and quality of breast milk. Furthermore, a small fraction of the hormones in OC's has been identified in the milk of mothers on OC's; effects, if any, on the breast-fed child have not been determined. If feasible, defer OC's until infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OC's. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Pap smear and relevant laboratory tests.

As a general rule OC's should not be prescribed for longer than 1 year without another physical examination.

2. Under influence of estrogen-progestogen preparations, pre-existing uterine leiomyomata may increase in size.

3. Patients with history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while on OC's should stop OC's and use an alternate method to try to determine whether the symptom is drug-related.

4. OC's may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency.

5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while on OC's. If jaundice develops, OC's should be discontinued.

6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution.

7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. Clinical significance is undetermined.

8. Serum folate levels may be depressed by OC's. Since the pregnant woman is predisposed to development of folate deficiency and incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OC's, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency.

9. The pathologist should be advised of OC therapy when revelant specimens are submitted.

10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OC's: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling.

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis—See Warnings on carcinogenic potential of OC's.

Pregnancy—Category X. See Contraindications, Warnings.

Nursing Mothers—See Warnings.

Adverse Reactions—An increased risk of these serious adverse reactions has been associated with use of OC's (see Warnings): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.

There is evidence of an association between the following conditions and use of OC's although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients on OC's and are believed to be drug-related: nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea, amenorrhea during and after treatment, temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement, and secretion; change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening), intolerance to contact lenses.

The following adverse reactions have been reported in users of OC's, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OC's by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Fetal and neonatal cardiovascular complications from β-sympathomimetic therapy for tocolysis

Vern L. Katz, MD, and John W. Seeds, MD

Chapel Hill, North Carolina

β-Sympathomimetic drugs cross the placenta freely. Just as these agents cause serious cardiovascular changes in the mother, they may cause severe cardiovascular complications in the fetus. β-Sympathomimetic agents for tocolysis have been associated with fetal heart rate and rhythm disturbances, hydrops, stillbirth, neonatal cardiac failure, myocardial ischemia and infarction, and neonatal death. Prospective studies have documented changes in interventricular septa of babies exposed to these drugs. Histologic changes have been reproduced in animal models and in vitro similar to those seen in infants with myocardial disease caused by β-mimetic therapy. The mechanism of β-mimetic toxicity appears to be increased myocardial intracellular calcium leading to overexcitation and cell necrosis. Since serious fetal cardiovascular effects may occur with β-mimetic use, benefits should clearly outweigh risks before these drugs are administered. (AM J OBSTET GYNECOL 1989;161:1-4.)

Key words: β-Sympathomimetics, fetal cardiac, tocolysis introduction

The use of β-sympathomimetics for tocolysis is now a mainstay in the prevention of premature birth. Unfortunately, these agents have potent cardiovascular effects. Attention to the adverse cardiovascular effects has focused primarily on the mother. However, serious cardiovascular complications may also occur in the fetus.

In 1924 Pierce Rucker[1] presented a report on the "Action of Adrenalin on the pregnant uterus" to the Southern Medical Association. Using 5 minims of 1 to 1000 solution of adrenalin "hypodermically," he caused a "cessation or diminution" in uterine contractions in 16 of 20 gravid women. This investigation followed his earlier observation of decreased contractions with the administration of epinephrine HCl (Adrenalin) and procaine HCl (Novocain) in caudal anesthetics. His report appears to be the first investigation of the use of adrenergic agents for tocolysis. He did not describe at that time any effects from his injections on the fetus.

Sixty years later in 1983, Thomas Benedetti[2] reviewed maternal complications of β-sympathomimetic therapy and cautioned: "There is a long and sobering list of potentially life threatening complications . . . we must ask ourselves by whom and under what circumstances should these drugs be used."[2] Careful attention and rapid response to maternal cardiac signs and symptoms, electrocardiographic changes, and fluid and electrolyte balance have improved the maternal risk/benefit ratio. Evaluations of the fetal cardiac status during exposure to the same potentially toxic medications have been rare.[3] Fortunately, most infants appear to tolerate

Table I. Reports of cardiovascular complications

Author	*β-Sympathomimetic exposure*	*Complications*	*Treatment and outcome*
Brosset et al.[4]	Intravenous ritodrine 12 hr	Extrauterine superventricular tachycardia, cardiac failure	Digitalis, resolution of complications
Hermanse and Johnson[5]	Intravenous and oral ritodrine, 5 wk	In utero superventricular tachycardia	Delivery spontaneous, resolution of
Lenke and Trupin[6]	Intravenous terbutaline, 5 hr	Stillborn	—
Beitzke et al.[7]	Oral and inravenous ritodrine, 7 wk	In utero atrial flutter hydrops	Delivery, DC shock, digitalis, resolution of complication
Vogt et al.[8]	Intravenous fenoterol variable duration, series of 30 infants	Tachycardia, ECG changes, cardiomegaly, cardiac failure, perinatal death, myocardial infarction	Range from spontaneous resolution to neonatal death
Katz and Seeds	Intravenous ritodrine, oral terbutaline, 12 days	Hydrops, neonatal congestive failure, myocardial infarction	Delivery; digitalization; neonatal death

DC, Direct current; *ECG*, electrocardiographic.

β-mimetic exposure without problems, but a growing number of reports document serious fetal cardiac complications from β-mimetic therapy.[3-12, 14-16] The purpose of this article is to summarize and illustrate fetal cardiovascular complications of exposure to β-sympathomimetics and review the relevant literature regarding fetal cardiotoxicity from these drugs.

Prospective evaluation of fetal cardiovascular complications caused by β-mimetic therapy

Nuchpuckdee et al.[11] used M-mode echocardiography to assess newborn cardiac status in 41 infants whose mothers had been treated with ritodrine from 1 day to 7 weeks (mean, 16 days). Compared with control infants matched for gestational age, infants of ritodrine-treated mothers had disproportional septal hypertrophy. Interventricular septal thickening correlated ($r = 0.96$) with the duration of ritodrine use by the mother. All echocardiographic changes were gone within 3 months of age. The clinical outcomes were not different between the two groups.

Crawford et al.[12] performed echocardiograms on 34 infants exposed to β-mimetics in utero for tocolysis and compared them with controls. They also demonstrated a significant increase in interventricular septal thickness.[12]

Bohm and Adler[10] examined autopsy specimens of fetuses and newborns dying of noncardiac causes whose mothers were exposed to β-mimetic therapy (from 1 day to 12 weeks' duration). Autopsy specimens from gestational age–matched control subjects not receiving tocolysis were also reviewed. In 20 of 25 autopsy specimens from the β-mimetic exposed group, pathologic changes of myocardial ischemia and infarction were found. None of these changes were seen in the control group. These changes were classified as focal necrosis, fatty degeneration, and myocardial cell nuclear enlargement, primarily of the right ventricle.[10] The histopathologic findings at autopsy of the case presented below are entirely analogous to these changes.

Mechanism of β-mimetic toxicity to the fetal cardiovascular system

The cardiovascular complications described in case reports and prospective studies have a natural model. Catecholamine overload leading to cardiomyopathy, myocarditis, and necrosis is a well-understood phenomenon. Pheochromocytoma provides a pathologic model of this toxicity.[13-15] Elevated and prolonged exposure of the heart to catecholamines leads to cardiomyopathy, myocarditis, and infarction similar to that seen with β-mimetic therapy. In the case of tocolysis, the fetus is exposed to β-sympathomimetic drugs that cause prolonged and elevated activation of the adrenergic receptors.

Animal models have helped clarify the mechanism of myocardial damage.[13-16] The catecholamines or sympathomimetics affect the myocardial cells by increasing the flow of calcium through the cellular and intercellular membranes. Increased calcium leads to increased cellular metabolism and increased cardiac activity. The next step is a growing imbalance between oxygen supply and consumption. Structural integrity of the cell is lost and necrosis occurs.[14-16] Isoproternol, norepinephrine, and fenoterol have been used to create these lesions in vitro and in vivo in rats and dogs.[13-16]

An in vitro study used fetal myocardial tissue from abortuses, exposing the fetal myocardium to fenoterol. Focal parenchymal necrosis developed, and histologic changes similar to those seen in infants exposed in utero to β-sympathomimetics for tocolysis were documented.[10, 15] A calcium channel blocker (verapamil)

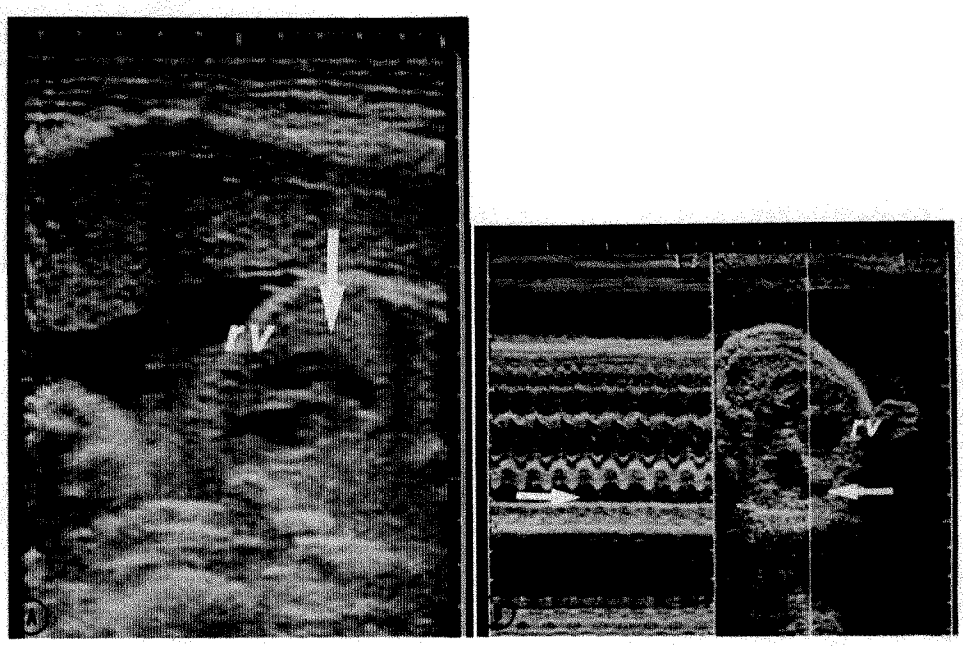

Fig. 1. A, Ultrasound scan of a transverse section of fetal chest, four-chamber view, before tocolytic therapy. *Arrow* points to fetal heart. **B,** M-mode echocardiogram of fetus 12 days after initiation of β-sympathomimetic therapy for tocolysis. Heart is now enlarged from **A,** and ventricles are dilated. Polyhydramnios is also present. *Arrows* point to pericardial effusion. *rv,* Right ventricles.

was added to the media and myocardial necrosis was prevented.[15] In fact, the combined use of β-mimetics and calcium channel blockers, usually verapamil, is now widely accepted in Europe. This practice was originally introduced to prevent unwanted maternal cardiovascular side effects.[16]

Most of the cardiovascular effects are initially transient and reversible.[14] However, the most severe changes of widespread cellular necrosis may lead to heart failure and death. The right ventricle, the area of greatest cardiac work in the fetus, appears most seriously affected by tocolytic medications. Myocardial damage is dose related, and the severity of changes is also related to the duration of exposure. The model of catecholamine or β-sympathomimetic overload leading to increased intracellular calcium and cellular necrosis matches the clinical picture of fetal myocardial toxicity caused by tocolytic therapy with β-mimetics.

Reports of fetal cardiac complications associated with β-sympathomimetic tocolysis

β-Sympathomimetic agents freely cross the human placenta and may be found in concentrations in umbilical cord serum equal to maternal serum.[3] Thus it is not surprising that fetuses and newborns have cardiac complications similar to adults exposed to these drugs. Myocardial ischemia, injury, and infarctions are well documented in mothers exposed to these agents.[2]

Elevations in baseline fetal heart rate from maternal β-sympathomimetic administration is a widely accepted side effect and not necessarily a complication. Complications are viewed as pathologic effects leading to potential compromise. A wide spectrum of fetal cardiovascular complications have been reported in association with β-sympathomimetic use for tocolysis. Fetuses and newborns have been reported to have rate and rhythm disturbances, including paroxysmal superventricular tachycardia and atrial flutter.[4, 5, 8] These lesions have typically resolved spontaneously within a few days to 2 weeks. Electrocardiographic abnormalities reported include transient nonspecific T wave changes and ischemic T wave changes.[4, 5, 7, 8] Vogt et al.[8] reported on a series of 30 infants admitted with cardiac disease after treatment with fenoterol. The spectrum of neonatal disease ranged from T wave changes to myocardial infarction. More serious fetal complications, including hydrops fetalis, pulmonary edema, and extrauterine cardiac failure, have also been seen.[4, 7, 8] Severe complications have included stillbirth, neonatal death, and histologic findings of myocardial infarction.[6, 8-10]

Table I lists cases of cardiovascular complications directly related to β-sympathomimetic therapy for tocolysis. In addition to the 34 cases listed in Table I, we recently cared for an infant who developed hydrops from a myocardial infarction in utero presumably caused by β-sympathomimetic therapy. The infant's mother, a 31-year-old gravida 2, para 0 white, was treated at 28 weeks' gestation for preterm labor. She

was given intravenous ritodrine, 15 μg/hr, for 2 hours and then 2.5 and 3.75 mg of oral terbutaline every 4 hours for 12 days. Fig. 1, *A*, shows the normal cardiac ultrasound study of the fetus before therapy. Fig. 1, *B*, shows the dilated heart 12 days after therapy was initiated. Pericardial effusion, cardiomegaly, and paradoxical interventricular septal motion were also noted on ultrasound examination. The infant was delivered and died on day 3. Results of viral cultures, inoculates, and titers were negative. The placenta was normal. The autopsy showed large areas of myocardial necrosis with calcification, primarily subendocardial and in the right ventricle. These findings were identical to those of Bohm and Adler[10] and Vogt et al.[8]

The cardiac complications reported in Table I mirror the spectrum of cardiovascular complications seen in mothers given β-sympathomimetics for tocolysis.[2] However, fetal cardiovascular complications may be underreported, since premature infants (exposed and unexposed) to β-sympathomimetics agents suffer from multiple problems that may overshadow β-sympathomimetic effects.[9, 10]

Comment

β-Sympathomimetics have been used for tocolysis for well over a decade. An estimation of the incidence of serious complications is difficult to make. Severe fetal cardiovascular complications are rare, but subclinical pathophysiologic changes seem to occur more commonly. Direct myocardial effects, including tachycardia, are usually transient. Interventricular septal hypertrophy in infants exposed to longer durations of tocolytic therapy seems to be reversible. Reports of severe and permanent myocardial damage leading to cardiac failure and perinatal mortality as described in our review are rare. Studies from multiple institutions would be needed to arrive at an absolute risk. However, in view of current knowledge, it is prudent to recommend careful consideration and evaluation of the risk/benefit ratio of the use of β-sympathomimetics in every case and consider alternatives with less cardiotoxic potential.

It appears appropriate to use β-sympathomimetics for limited duration and only when there is a very clear benefit to be gained. Use of these drugs beyond 33 completed weeks of gestation should only be considered after careful evaluation of alternatives and rarely prescribed solely for contractions without cervical change. When β-sympathomimetics are used, regular ultrasound examinations during and after the time of drug exposure to evaluate for early fetal cardiac changes should be considered. Ultrasound examinations should include measurements of biventricular end-diastolic diameter and interventricular septal thickness. This article emphasizes that serious potential effects may occur from the use of β-sympathomimetics. Benefits should outweigh risks before these potent agents are prescribed.

Understanding and eliminating errors in perinatal research

Barry S. Block, MS, MD
Chicago, Illinois

Research studies published in the scientific literature have had a rapid impact on medical practice, especially in clinical obstetrics. Recently, incentives to control medical costs without sacrificing the quality of care have placed increased importance on studies that truly demonstrate clinical effectiveness. In addition, there are ethical concerns that improperly designed or conducted studies adversely affect medical practice and place patients at unnecessary risk. This article summarizes potential sources of error and encourages the valid interpretation of the results and conclusions of experimental studies by making four suggestions: (1) the errors and limitations that may be present in the methodology should be described and explanations given how the errors might have affected the results and why the limitations are acceptable; (2) the methods selected should allow an answer to the question proposed; (3) the investigator should verify that the appropriate statistical test is used; and (4) when unexpected or hard to explain results are found, verification before publication should be undertaken. (Am J Obstet Gynecol 1989;161:5-9.)

Key words: Quality control, research design, statistics

Avoiding errors in the performance of experimental studies and the interpretation of the results and conclusions of such studies is especially important in clinical obstetrics. Bryce and Enkin[1] have described the vital role that perinatal clinicians have ". . . in evaluating the treatments we are now using, as well as new therapies in the future." Similarly, Tyson et al.[2] have stated that "adequate evaluation of (treatment) methods prior to their recommendation is needed to avoid widespread use of ineffective or hazardous treatment methods especially if high-risk (perinatal) patients are involved." Recent emphasis on the need to control medical costs without sacrificing the quality of care places increased importance on studies that truly demonstrate clinical effectiveness. Improperly conducted studies cost money, patients may be placed at risk by an inferior treatment, and animals may be killed to collect data that are incorrectly interpreted. Finally, as stated by Altman,[3] ". . . it is unethical to publish results that are incorrect or misleading." Several authors have addressed the issue of proper statistical design and analysis in previously published reports[2, 4, 5]; however, other issues remain. As stated by Feinstein,[4] ". . . the most important issues in biostatistics are not expressed with statistical procedures. The issues are inherently scientific, rather than purely statistical. . . ." Two examples of such scientific issues are (1) the theory of error and (2) the consideration of alternative conclusions after the statistical analysis is completed.

The ultimate responsibility for avoiding errors rests with the individual researcher, but reviewers and readers of scientific articles also have an important responsibility. After recent reports of academic fraud,[6] the reliability and integrity of scientific publications are under review. All investigators, including perinatal researchers, are influenced by the sophistication of our technical procedures and the intense competition for academic achievement. All of us must make a commitment to eliminate fraudulent or incorrect publications from the literature. The purpose of this article is to assist investigators, reviewers, and readers by reinforcing existing knowledge of the principles of error theory and by encouraging the valid interpretation of the results of experimental studies. Examples presented are chosen from publications in the perinatal literature.

Error theory[7]—definition of terms

The term "error" generally has two usages. First, it may refer to the difference between a measurement and the "true" value, and second, it may refer to the estimated uncertainty in an experiment. The term is frequently used improperly to denote a "discrepancy," that is, the difference between two measurements. There are two principal types of errors: determinant errors, or errors that can be evaluated by a theoretic or experimental procedure, and indeterminate errors that can not be so evaluated.

Errors that are differences between a measurement and a "true" value are classified as systematic, random, or illegitimate and are summarized in Table I. Systematic errors in measurement depend on the skill of the observer and include calibration errors, human errors, errors from experimental conditions, dynamic re-

Table I. The classification of errors that represent differences between a measurement and a true value

Type of error	*Cause*	*Example*
Systematic errors		
Calibration error	Incorrect calibration or "zero" drift with time	Thermometer that reads 101° F in boiling water
Human error	Observer bias; also called personal errors	Head position when reading a pH meter scale
Experimental conditions	Change in conditions from those during calibration	Temperature or pressure is different than during a calibration
Dynamic response error	Exceeding the design of the equipment	Nonlinear response to a fast changing signal
Imperfect technique	Loss of sample during collection	Splashing during 24 hr urine collection
Random errors		
Error of judgment	Observer estimates that vary from time to time	Reading fetal heart rate tracings at 3:00 AM when overtired
Fluctuating conditions	Temperature, pressure or line voltage variations	Power "brown out"
Small disturbances	Mechanical disturbances from nearby equipment	Vibrations from adjacent centrifuge
Error of definition	What is being measured is not an "exact" quantity	Measuring one's height because of irregular surfaces
Illegitimate errors		
Method error	Wrong or insufficient experimental method	Self-explanatory
Instrument error	Faulty instrument or misoperation	Use of outdated equipment
Blunder	Outright mistakes in reading instrument	Inadequate training of assistants
Error of computation	Arithmetic error during analysis	Error ("bug") in computer program or in data entry
Chaotic error	Disturbances that exceed natural random errors	Discontinue experiment until source is removed

sponse errors, and imperfect technique. Random errors include errors of judgment, fluctuating conditions, small disturbances, and errors of definition. They are caused by chance, and their elimination requires improving and refining experimental technique. Illegitimate errors, such as method errors, instrument errors, blunders, arithmetic errors, and chaotic errors, are avoidable errors that have no place in research publications.

Statistical terminology

The common uses of the statistical term "error" are summarized in Table II. Interestingly, the standard error is not an error and has nothing to do with standards. Similarly, the term "error variance" is also included in the statistical vocabulary but is a quantity that refers to observer variation not mistakes. The use of the term "error" is confusing, improper, and untrue but entrenched by time. Clearly, a better choice is dispersion or deviation rather than error.

Other uses of the term "error" include experimental error, observer error, and type I and II errors. Experimental error is introduced because a sample is taken from a large population. If the entire population were studied, the "true" value would be known. Experimental error is minimized by appropriate sample selection, and observation errors can be diminished by repeated observations by the observer. Experimental error can be biased or unbiased. If the ratio of observed error to sample size tends to zero as the sample size increases, the error is said to be unbiased. Also, the statistic calculated from the sample may be biased or unbiased and overestimate or underestimate the population parameter. If an experiment were repeated a large number of times and the statistic has the property that the estimations average out, then the statistic is said to be unbiased.

There are two ways that an investigator can make a mistake in hypothesis testing—rejecting a true hypothesis or accepting a false one. A type I error occurs if the hypothesis under test is rejected when in fact it is true. A type II error occurs if the hypothesis under test is accepted when in fact it is false. The p value is frequently, although incorrectly, thought to be either the probability of making a mistake or the importance of the difference observed. The p value is, by definition, the probability of obtaining an equally unlikely result if the hypothesis under test were actually true.

Statistical power is the probability of rejecting a null hypothesis when in fact it is false and should be rejected. In hypothesis testing the magnitude of difference that would lead to rejection of the hypothesis (D), the probability of committing a type I error (α), the probability of committing a type II error (β), and the sample size (n) are directly related. If any three (D, α, β, or n) are known, then the fourth is fixed mathematically. In a properly designed study the magnitude of the difference one desires to detect, α and the power

Table II. A description of some statistical uses of the term "error"

Statistical term	*Definition*
Absolute deviation	Absolute value of a deviation from the mean
Average deviation	Sum of absolute deviations divided by sample size
Fractional error	Ratio of absolute deviation to expected value
Percentage error	Fractional error expressed as a percentage
Probable error	That magnitude of deviation whose probability of being exceeded is one half
Standard deviation	Positive square root of sum of square deviations from mean divided by sample size less 1
Standard error	Standard deviation divided by square root of sample size
Error variance	Sum of square deviations from group mean divided by number of groups less 1
Error tolerance	Region with a given probability of containing "true" value

(1-β), are preselected, and the size of the sample required is then determined in advance. Failure to follow these guidelines may lead to a negative conclusion with low statistical power in which no effect was found but in which there was little if any chance of detecting an effect.

The terms "precision" and "accuracy" are used to describe how well measurements relate to each other and to the "true" value. Precision is a measure of reliability or how reproducible the results are. An experiment with small random errors has high precision, and the more precise of two measurements is the one with the smaller probable error. Accuracy is a measure of how close the experimental result comes to the "true" value. An experiment with small systematic errors has high accuracy. For a diagnostic test, the accuracy is the total number of correct diagnoses of both disease and nondisease divided by the number of tests performed.

Error tolerance is described in Table II. In layman terms, the confidence limits are an interval with a given likelihood of including a population parameter, such as the population mean or population variance. For example, if all possible samples of size n were taken from a population and a 90% confidence limit of the mean calculated from each sample, the population mean would be contained in 90% of the intervals. These limits apply only to samples of size n but are frequently used incorrectly and also applied to an individual value. The correct region for including a specified proportion of the individual values from a population is called the tolerance limits. For example, considering gestational age and biparietal diameter measurements obtained by ultrasound study, one may claim with 95% confidence that at least 90% of individual values will be between given limits. In summary, tolerance limits pertain to individual values, whereas confidence limits pertain to parameter estimates obtained from a sample of size n.

The expression "statistical significance" is generally both misunderstood and misused. Unfortunately, there is a tendency to equate significance in a statistical sense with clinical or medical importance. Actually, a small difference of no clinical importance may be statistically significant and an important clinical difference may not be statistically significant depending on the sample size selected. A statistically significant result should be thought of as representing evidence of rather than proof of a particular hypothesis, just as a positive test result does not prove that a patient has a disease. Similarly, a nonsignificant result does not imply nonimportance or nonexistence and would better be thought of as inconclusive or not proved. The choice of the statistical term "significance" was unfortunate. The misconception arises from a misunderstanding of the precise meaning of the term "p value." A significant p value, usually $p < 0.05$, is only a guide to interpretation and is not meant to be a strict rule. In fact, to accept as real a statistically significant result at the $p < 0.05$ level is both unwise and unfounded because one in 20 comparisons of equally effective treatments will be significant by definition.

When the p value is significant, an explanation other than that there is a "true" difference may be present. The difference may be explained by an artifact or the hidden association with a third factor. Artifacts can be caused by chance or bias. The statistical analysis quantifies the probability of obtaining a particular result by chance alone if the hypothesis is true. If the probability is low, the investigator rejects the hypothesis, accepting that there is a real risk of being wrong. Bias, if present, may explain a significant finding between equally effective treatments. Bias is particularly likely to occur in retrospective studies in which data are frequently analyzed in the search for significant results. Bias may occur in the selection of the treatment group, the control group, interpretation of the findings by chart review, or patient recall. Another explanation for an apparent correlation between two factors is that a hidden third factor is present, also called confounding effects. That is, two factors appear to be correlated; however, the explanation is their relationship with a third factor.

For example, a study of income and height would demonstrate a significant correlation. However, it is the relationship of sex with income (males earn more) and the relationship of height with sex that explains the finding.

Violations of underlying assumptions

Statistical tests are based on underlying assumptions, and each individual test may have a different set of underlying assumptions. For example, for the Student *t* test, the underlying assumptions are that the data are independent random samples from normal distributions with equal variances. With little reason to expect otherwise, one often assumes the deviations from these assumptions, if they exist, are small. The robustness of a statistical test is its property of maintaining the same proportion of type I errors when the underlying assumptions are violated as when they are true. Care is required because knowingly or unknowingly violating, these assumptions may lead to the wrong interpretation of the results and incorrect conclusions. Independence implies that the samples are not related. There can be no more than n independent measurements and n-1 degrees of freedom with n subjects. Randomization is the process used to obtain a sample—not the sample itself. In most clinical studies, patient selection is strongly biased. Patients with a disease choose the physician rather then the other way around. Data may be contaminated because of differences in diagnostic criteria or the presence of coexisting disorders. Also, a control group selected from hospitalized patients without the disease may also be biased. A normal or Gaussian distribution is usually assumed. However, obvious signs of nonnormality or skewness should be investigated. For example, if the mean and standard deviation of a measurement that can take only nonnegative values are of the same magnitude, the distribution cannot be Gaussian. Furthermore, if A and B are continuous normal distributions, the ratio A/B will not be normally distributed. The problems related to violations of the underlying assumptions can be avoided by selection of a nonparametric or other appropriate technique. If the variance increases with increases in the independent variable or if the distribution is nonnormal, transformation of the data may be helpful.

Anticipating and avoiding errors

Investigators can aid readers by providing a clear concise accounting of what they did, what they found, and what they conclude. They should anticipate reader concerns by describing errors or limitations that may be present in the methodology and explaining how the errors might have affected the results and why the limitations are acceptable. Before publication, the investigators should assess the validity of any assumptions they made and consider alternative hypotheses to explain their findings. In addition, the investigators should verify that the data and methods support their conclusion and that an appropriate statistical test was used. In the event that unexpected or hard to explain observations occur, verification before publication should be undertaken. To illustrate that improper patient selection may lead to a wrong conclusion and relate actual publications to the principles described herein, several examples are presented.

As previously stated, the methods selected must allow an answer to the question proposed. For example, Crombleholme et al.[8] found an increase in term births from 15.5% to 68.5% in patients whom they treated with cervical cerclage who had previous obstetric losses without a typical history of an incompetent cervix. They concluded that cervical cerclage improves outcome in patients with previous obstetric loss. However, Harger[9] noted the fallacy of using patients who were selected because of poor reproductive performance as their own controls. He presented data that demonstrated a successful outcome of 79% in a similar group of patients who were not treated by a cervical cerclage procedure. Harger was concerned because Crombleholme et al. did not follow a comparable group of patients who were untreated, and it is unclear whether the cervical cerclage procedure might even have decreased successful outcomes, perhaps from 79% to 69%. At the least, even in the event no difference in outcomes were found, the expense, morbidity, and risk of unnecessary surgery should be cause for concern.

The investigator should verify that the appropriate statistical test was used to avoid publishing misleading results. For example, Kennedy and Greenwald[10] investigated the relationship between cesarean section for cephalopelvic disproportion and shoe size and found that women less than 5 feet tall who wore a shoe size less than 5½ had a twofold increased risk of cesarean section with a $p < 0.05$ with the use of χ^2 test. Muncie[11] correctly noted that the proper statistical test is Fisher's exact test and that the probability calculated is $p = 0.498$, a nonsignificant result.

When unexpected or hard to explain results are found, caution is advised and verification before publication should be undertaken. This point is demonstrated by the following two examples. In the first example, Edem et al.[12] investigated the urinary protein profile in hypertensive pregnancies with nephelometry. They noted that "it was very surprising to find that the concentration of albumin and transferrin became nondetectable by nephelometric measurement with increasing severity of pregnancy-induced hypertension." van Kamp et al.[13] observed similar findings that were

at variance with the results of protein electrophoresis performed on the same urine samples. Before publication of their data, they investigated further and found that the concentration of albumin was so high that the antigen excess caused soluble complexes to form, resulting in low scatter and an "out of range, low" message on the nephelometer. They strongly suggested that preliminary protein electrophoresis be performed to determine the proper dilution so that ". . . false conclusions about the absence of 'hidden' proteins are avoided."

In the second example, Lueck et al.[14] presented an ". . . initial descriptive report of observations of multiple forms of an organism found in patients with gestational trophoblastic disease and in patients with preeclampsia-eclampsia," but noted that ". . . The taxonomy of these forms has not yet been determined." Long et al.[15] repeated the study and found ". . . that the objects described by Lueck et al. are artifacts created by cotton or other cellulose fibers and are unrelated to disease."

Comment

There are several ethical concerns about research that is substandard, including the misallocation of resources, as well as the investigator's time, the inconvenience and unjustified risks to which patients are exposed, and the likelihood that publication of misleading results might falsely influence medical practice and lead to unnecessary further work. There are many reasons why erroneous publications may have been intenally or unintentionally submitted. To avoid misrepresenting scientific data, individual researchers and research institutions and universities must meet their obligation to submit only truthful publications. To avoid unintentional errors, researchers must ensure that experiments are well designed and properly evaluated.

A case-control study of epithelial ovarian cancer

Patricia Hartge, ScD,[a] Mark H. Schiffman, MD,[a] Robert Hoover, MD,[a] Larry McGowan, MD,[b] Linda Lesher, MHS,[b] and Henry J. Norris, MD[c]

Bethesda, Maryland, and Washington, D.C.

With data from a study of 296 patients with primary epithelial ovarian cancer and 343 patients hospitalized because of other conditions, we estimated ovarian cancer risk in accordance with reproductive and other factors. Risk was greatest among women of lower parity, especially among women who said they planned to have children but could not. The protective effect of oral contraceptives seen in other studies was observed only in subgroups of our study population. Women who had breastfed their children had decreased risk, but the number of months of breastfeeding was not related to risk. Incomplete pregnancies did not provide the protection seen for live births. A family history of ovarian cancer and a medical history of breast cancer were both strong risk factors. None of the nonreproductive factors that we examined, including childhood illnesses, tobacco and alcohol consumption, obesity, and selected adult diseases, was convincingly associated with risk. (Am J Obstet Gynecol 1989;161:10-6.)

Key words: Ovarian cancer, endogenous estrogens, infertility, oral contraceptives, epidemiology

The causes of ovarian cancer are mainly unknown.[1, 2, 3] Known risk factors are age (incidence rises until about age 60 years), race (white women are at higher risk than nonwhite women), low parity, infertility, a history of endometrial or breast cancer, a family history of ovarian cancer, and exposure to radiation. Probable protective factors are oral contraceptives and surgical menopause. Although the importance of reproductive and contraceptive history has been firmly established, questions remain. How do parity, pregnancy, and fetal loss jointly affect risk? Does the timing of the first birth affect risk? Is infertility an independent risk factor, separate from the effects of low parity? In addition, many nonreproductive factors have been suggested. With interview and medical records data from a case-control study, we have estimated ovarian cancer risk according to various reproductive and other suggested risk factors to add to our knowledge with regard to these persistent issues.

Methods

Study methods are described in detail elsewhere.[4] All eligible cases involved women aged 20 to 79 years who resided in the Washington, D.C., metropolitan area and who were first diagnosed by operation with microscopically confirmed primary epithelial ovarian cancer during the period August 1978 to June 1981. Cases included tumors of low malignant potential as well as frankly malignant tumors because risk factors for the two groups were similar.[5] For all participants with ovarian cancer, we obtained the diagnostic microscopic slides and pertinent medical records. After review we excluded 30 women found not to have definite primary ovarian cancer of the epithelial type by microscopic (H.J.N.) or clinical (L.M.) evaluation. Several of these cases had been classified as mucinous ovarian cancer but actually were of colorectal origin.

We identified 400 cases and interviewed 296 women (74%). Losses were a result of death (n = 44), disability (n = 12), physician's refusal (n = 8), patient's refusal (n = 33), or other reasons (n = 7). As shown in Table I, serous and endometrioid types predominated.

Control participants were identified from hospital discharge lists and were matched with women with epithelial ovarian cancer according to hospital, age, and race (Table II). A woman was not eligible to be a control if her discharge diagnosis was psychiatric or was potentially related to the major exposures of interest. For all potential control participants, we confirmed in the physician and hospital records that the women had at least one ovary intact and excluded those who did not because they were not at risk of ovarian cancer. We identified 439 controls of whom we interviewed 343 (78%). Losses were a result of death (n = 13), disability (n = 8), physician's refusal (n = 11), patient's refusal (n = 50), or other reasons (n = 14).

Trained, experienced medical interviewers obtained informed consent and administered a standardized questionnaire in the study participant's home shortly after diagnosis. (Questionnaire is available on request.)

Effects of ovarian cancer risk were measured by the

estimated rate ratio—the ratio of ovarian cancer incidence in an exposed group to that in the corresponding unexposed group. A rate ratio of 2.0 for nulliparity, for example, indicates that the incidence rate is twice as great among the nulliparous women as among the parous women; conversely, a rate ratio of 0.5 indicates that the incidence is half as great. The rate ratio estimates were adjusted for the effects of confounding variables by stratified contingency table analysis (presented in the tables) and by logistic regression models, which gave similar results.[6] All trend tests used scored categorized data and were two-tailed.

For each estimate presented we adjusted for age and race. We assessed whether there were confounding effects of parity, difficulty conceiving, recent administration of oral contraceptives, surgical menopause, menopausal estrogen use, or family history of ovarian cancer, and we adjusted the estimates accordingly. If the number of confounders held constant exceeded three, we used a logistic regression model to produce smoothed estimates.

To derive unbiased estimates of the effects of tobacco, alcohol, and adult medical conditions, it was necessary to include in the control group only women who were admitted for conditions not caused by (or protected by) the exposure under assessment. Without such exclusions, a hospital-based control series would produce spurious results because the population of hospitalized women generally includes, for example, more smokers than the whole population of women at risk for ovarian cancer.

Results

A total of 12% of the patients with ovarian cancer and 14% of the controls were black, and the remainder were white. The mean age at diagnosis was 54.4 years among women with cancer and 54.7 years among controls. Because the control participants were chosen from the same hospitals as were the women with cancer, they were similar in social class and religion.

Greater parity was related to reduced risk in our study (Table III), and pregnancies that ended in spontaneous or induced abortion or stillbirth did not, as a group, confer any protection. When the effects of the different pregnancy outcomes were further separated, stillbirths appeared to increase risk, induced abortions appeared to slightly decrease risk, and spontaneous abortions appeared not to affect risk, but the estimates for the specific outcomes were rather unstable. There was also no clear pattern of risk when women were categorized according to the number of months pregnant with the different outcomes, adjusted for the effects of parity. It was necessary to adjust for the effects of parity in the examination of fetal loss because the two were correlated: about one fifth of the nulliparous women had some fetal loss, whereas about one half of the women with five or more live births had fetal loss. The strong protective effect of parity was seen in almost all subgroups and was strongest among women aged 20 to 39 years and weakest among those aged 60 to 79 years.

The protection afforded by greater parity was not explained by an effect of earlier first birth. On the other hand, as shown in Table IV, the apparent protection associated with earlier first birth, when this variable was considered alone, was eliminated by adjusting for parity. Also shown in Table IV is reduced risk among women who had breastfed their children, but an erratic relationship is shown between lifetime months of breastfeeding and risk.

The total group of women who had taken oral contraceptives showed no altered risk (Table V), but women who had taken them ≥3 years were at slightly reduced risk, as were women who had taken them recently. Women who took compounds with high levels of progestogen showed no excess ovarian cancer risk (data not shown). Those who quit after only 1 or 2 months, usually because of side effects, were not at

increased risk. The effect of oral contraceptives was similar for parous and nulliparous women, but it varied somewhat with age at diagnosis. Among women younger than 40 years old, oral contraceptives were weakly protective (rate ratio = 0.7), but among women aged 40 to 59 years, they were not (rate ratio = 1.1). Only one woman older than 59 years of age had taken oral contraceptives.

The effects of infertility were assessed in several ways. Married nulliparous women had a 70% higher risk than unmarried nulliparous women, an excess relative risk that was limited to those who reported difficulty conceiving (Table VI). Among the married nulliparous participants there was little difference in risk between those who had been pregnant and those who had not. In a separate confirmatory question, we asked married women who had never conceived why they had never been pregnant. Women who planned not to have children showed no increased risk compared with nonmarried nulliparous women (rate ratio = 1.0, 95% confidence interval = 0.4 to 2.4) but women who were unable to become pregnant had a corresponding rate ratio of 2.8 (95% confidence interval = 1.1 to 7.3). So few women reported each specific cause of infertility with confirmation by a physician that cause-specific estimates were quite unstable. Among parous women, a history of trouble conceiving was unrelated to risk (Table VI).

Participants were asked about a variety of medical factors found in previous studies to be related to risk of ovarian cancer. Our data on menopausal factors,

including protective effects of hysterectomy and menopausal estrogen, are detailed elsewhere. The results for selected childhood and adult diseases are given in Table VII. None of the childhood diseases influenced risk, regardless of whether it occurred before, after, or around the time of menarche. An extensive analysis of mumps revealed only that the protective effect of parity was absent among women who did not recall having had mumps.

Among the adult diseases, shingles was significantly protective but chickenpox was not. High blood pressure was weakly associated with increased risk. Thyroid disease was apparently protective, and hyperthyroidism was more protective than hypothyroidism (rate ratio = 0.5 and 0.9, respectively), but patients could not reliably make this distinction. Adrenal disease was reported by five women in the control group but no patients with cancer reported it. Diabetes was weakly protective. A history of asthma was also protective, but the effects of the illness and the asthma medication could not be distinguished because nearly all women with asthma had taken multiple medicines for their condition. Previous breast cancer was strongly related to risk but nulliparity, a strong risk factor for breast cancer and ovarian cancer, was present in only one of the 17 cases with previous breast cancer. There were only two histories of endometrial cancer among patients with cancer compared with four in the control group, a difference that was not statistically significant.

A family history of ovarian cancer in a sister, daughter or mother was reported by 13 patients with cancer and by only five women in the control group, which equals an elevated rate ratio of 3.3 (95% confidence interval = 1.1 to 9.4). No excess risks were seen for first-degree family histories of breast or endometrial cancer.

Obesity was not related to risk. We considered usual adult weight adjusted for height using Quetelet's index (weight ÷ height^2) divided into quartiles. The rate ra-

tios in increasing quartiles were 1.0, 1.4, 1.0, and 1.1, respectively.

As shown in Table VIII, ovarian cancer risk was related to drinking but was not related to cigarette smoking. Alcohol use was measured as the typical weekly number of shot glasses of alcohol, bottles of beer, and glasses of wine consumed over the past 10 years, with total alcohol consumption computed as the sum of the three subtotals. The rate ratio rose slightly with increasing total alcohol consumption, and with each of the three kinds of alcohol considered separately. The rate ratios were highest for whiskey (rate ratio = 1.6, 95% confidence interval = 1.1 to 2.3), followed by wine (rate ratio = 1.3, 95% confidence interval = 0.9 to 1.9) and beer (rate ratio = 1.1, 95% confidence interval = 0.7 to 1.6).

Comment

The results of this investigation confirm the importance of parity, infertility, family history, and previous breast cancer in the cause of epithelial ovarian cancer. The results also suggest the relative unimportance of some other factors associated with risk in previous epidemiologic investigations.

Several explanations of the protective effect of childbearing have been proffered, among them that pregnancy prevents ovulation, that it inhibits pituitary secretion of gonadotropins, or that an underlying problem leads both to low parity and increased risk. Estimation of the effects of different pregnancy outcomes may help reveal how childbearing reduces risk of ovarian cancer. If parity protected against ovarian cancer simply by the inhibition of ovulation, then a pregnancy would reduce risk approximately in proportion to its length, regardless of outcome. Our data suggest that pregnancies that lead to live births offer protection but those that lead to losses may not. Inasmuch as women with more live births tend to have had more losses, adjustment for parity is critical. One previous estimate of the rate ratio adjusted for parity was 0.8 per miscarriage.[7] Other investigations of fetal loss are not directly comparable, either because they were not adjusted for the effect of parity or because they measured the fraction of pregnancies that ended in

miscarriage rather than the number or months of various pregnancy outcomes.

Apart from the reduced risk associated with higher parity, there clearly seems to be a separate link between infertility and risk evident among the nulliparous women in our investigation. Previous studies have shown that married nulliparous women have a higher risk than single nulliparous women.[1,2] We clarified this observation by showing that married nulliparous women who chose not to become pregnant were not at increased risk, but women who tried and failed definitely were at increased risk. Case-control studies of ovarian cancer cannot easily assess infertility as a risk factor, because older women must recall often ill-defined diagnoses from decades earlier. One follow-up study of infertile women found increased ovarian cancer risk among subjects with nonhormonal infertility (rate ratio = 3.2, 95% confidence interval = 0.3 to 32.9),[8] but another did not.[9] Both studies observed very few cancers and both derived the expected rates of ovarian cancer from the general population of parous and nulliparous women, so the effects of parity and infertility could not be separated. A long-term follow-up study of a large cohort of infertile women could discriminate between the effects of different kinds of infertility and could provide useful etiologic clues. For example, anovulation that leads to infertility should protect against ovarian cancer if incessant ovulation is a key mechanism.

Several reproductive factors probably are not strongly related to risk. A majority of studies indicate that the number of live births and not their timing is the key factor. Our finding of reduced risk to women who breastfed their children confirms a previous observation[10] and supports the hypothesis that anovulation reduces risk. The absence of dose response may reflect the poor correlation between the number of months a woman breastfeeds and the months of ovulation suppression because of other factors such as body mass and variability in breastfeeding regimens. Menstrual factors such as age at menarche, menstrual symptoms, and age at menopause do not appear to be strongly related to risk of ovarian cancer in these or other data, although the plateau in age-specific incidence around menopause strongly suggests a change in risk broadly related to cessation of ovarian function. It is not clear whether menopausal estrogen use affects risk. Hysterectomy does appear to decrease risk, but the association may reflect increased clinical surveillance rather than decreased risk.[11]

An anomalous finding in this study was that women who take oral contraceptives had only a very slight reduction in ovarian cancer risk. The estimated rate ratios from many studies have been in the protective range of 0.5. to 0.7. We know of no biases in the current study that would distort our estimate of the effects of oral contraceptives. Other known risk factors showed the same patterns in this study as in other studies, and women with diagnoses potentially related to oral contraceptives were not selected as control participants. From all of the available data we infer that oral contraceptives protect some women from ovarian cancer.

A history of mumps infection has been found to be a weak protective factor in several previous investigations.[1,2] This effect, if real, is certainly not strong. The biologic meaning is in doubt because recall of mumps

history has been shown to be a poor indicator of antibody titer.[13] A careful examination of mumps exposure, assessed serologically, would be worthwhile. Most of the other childhood and adult diseases that we considered probably do not influence the development of ovarian cancer. The apparent protection conferred by a history of shingles, in the absence of an effect of chickenpox, has no ready explanation. Nor does the effect of asthma. The lack of effect of hypertension, obesity, or diabetes, accords with the inconsistent findings of previous studies. Two medical conditions that warrant further study are thyroid disease and adrenal disease. The examination of adult diseases as risk factors in a hospital-based case-control study is difficult because the control group should include only patients whose admission diagnosis is not related (positively or negatively) to the adult disease risk factor. Data from population-based studies with well-documented medical histories may clarify whether these two associations are real.

Women with a previous history of breast cancer were at substantially increased risk of ovarian cancer. This observation is not new[14] and appears to represent a true association. One goal of our painstaking pathologic and clinical review was to exclude metastatic breast and colon cancer; we believe misdiagnosis does not explain the finding. A family history of ovarian cancer seems to pose at least a three- to fourfold increased risk, as indicated by our results and the results of others.[2]

Smoking was not related to ovarian cancer in this investigation, as in most previous work, but the effects of alcohol remain unclear. Our study and others (e.g., Fasoli and Franceschi)[15] estimate slightly increased incidence of ovarian cancer among drinkers, but other studies of ovarian cancer found reduced incidence among drinkers (e.g., Gwinn et al. and Byers et al.).[16, 17] The available data suggest that if there is an association, it is weak.

During the past decade, case-control interview studies with 200 to 500 women with ovarian cancer have offered numerous leads. Comparisons among existing studies suggest that some of the leads warrant further pursuit. Despite their cost, larger studies are needed to give the statistical power to disentangle the effects of specific causes of infertility, varying paterns of oral contraceptives, and specific pregnancy outcomes.

Take the OC preference test.

1. In the United States last year, the OC group with the largest number of prescriptions was:

triphasic | low-dose monophasic | 1/50 formulations

2. In the last 18 months, more *new* prescriptions were dispensed for:

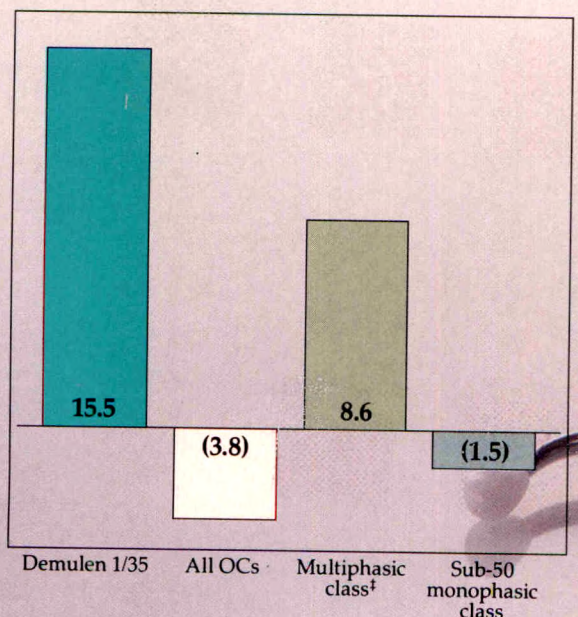
triphasics | low-dose monophasics

3. Which monophasic had an increase in new prescriptions 13 times the average of all low-dose monophasics in the last 18 months?

Demulen® 1/35* | Ortho-Novum® 1/35† | Lo/Ovral®‡

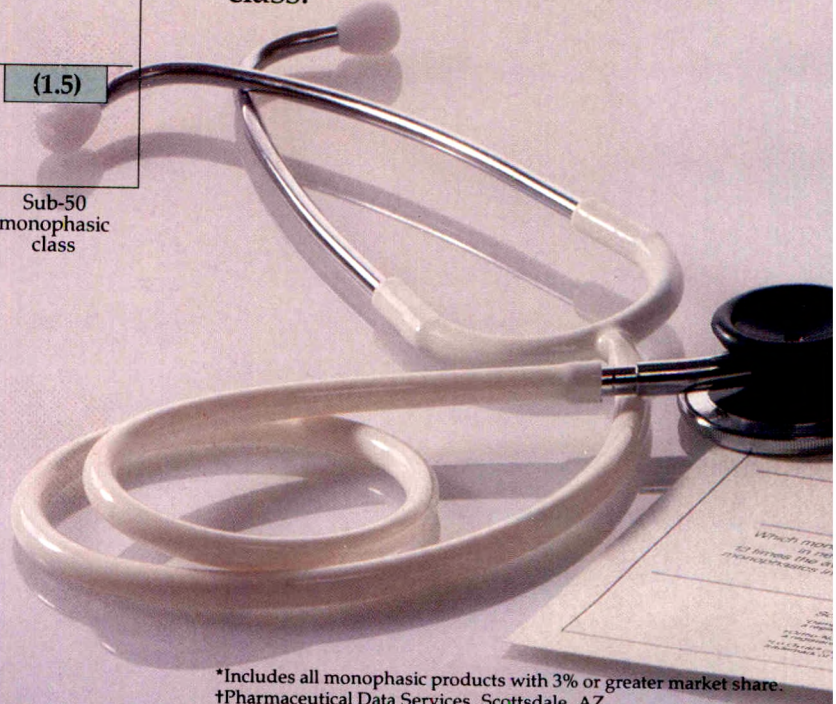
Scratch silver squares with a coin to reveal the answers.

*Demulen® 1/35 (ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg) is a registered trademark of G.D. Searle & Co.



†Ortho-Novum® 1/35 (norethindrone 1 mg, .035 mg ethinyl estradiol) is a registered trademark of Ortho Pharmaceutical Corporation.

‡Lo/Ovral® (norgestrel and ethinyl estradiol tablets) is a registered trademark of Wyeth-Ayerst.

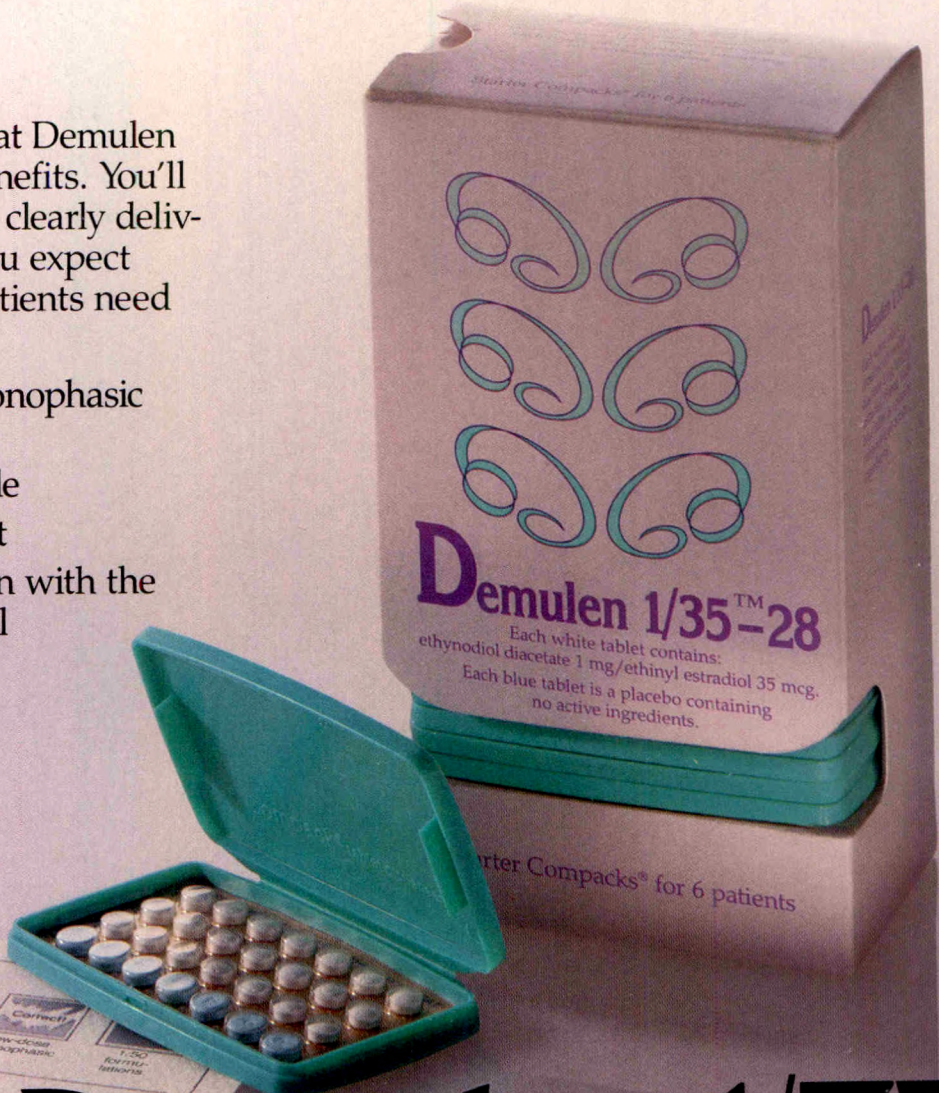


There's an OC in
and it's not

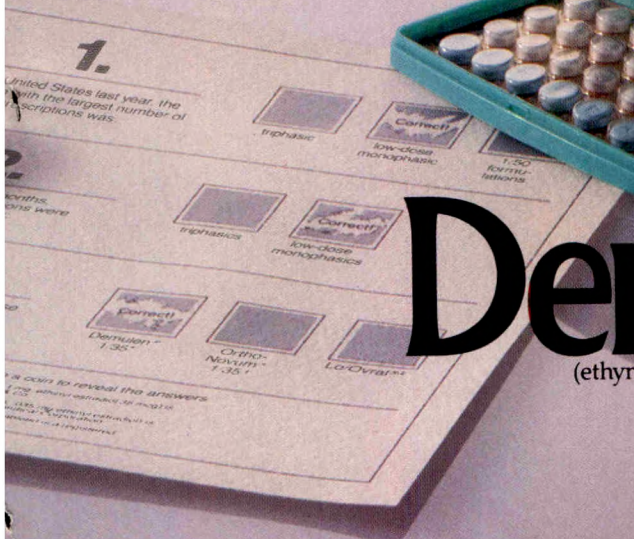
Now Demulen® 1/35 is the fastest growing monophasic*

New OC Rx's: *Percent change, October 1987 to March 1989†*

Today more and more physicians are taking an increased interest in Demulen 1/35 and prescribing it for their patients on oral contraceptive (OC) therapy. In fact, recent statistics show that new prescriptions for Demulen 1/35 rose by 16% during the last 18 months (October 1987 to March 1989).† That's a significantly greater increase than any other monophasic OC,* and nearly twice the growth rate of the multiphasic class.‡



*Includes all monophasic products with 3% or greater market share.
†Pharmaceutical Data Services, Scottsdale, AZ.
‡Data derived from the change (by percentage) in the number of new prescriptions for all multiphasic products combined, from October 1987 to March 1989.



The physician should become familiar with the full prescribing information (labeling) for this product, which discusses reported risks, such as thromboembolic disorders (including strokes and heart attacks) and hepatic lesions, as well as the need to monitor patients for early symptoms of any diseases or medical conditions, so use can be discontinued where appropriate. A brief summary of the prescribing information accompanies this advertisement.

a growth phase—
a triphasic.

Take a closer look at Demulen 1/35 and add up the benefits. You'll find that Demulen 1/35 clearly delivers the performance you expect and the results your patients need from an OC.

- ☐ Reliable low-dose monophasic therapy
- ☐ Low side-effect profile
- ☐ Minimal lipid impact
- ☐ Exclusive formulation with the progestogen ethynodiol diacetate

Demulen® 1/35

A89-A7450T

Demulen® 1/35

(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

Demulen 1/35™ Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 35 mcg. Each blue tablet in Demulen 1/35-28 is a placebo containing inert ingredients.

Demulen 1/50™ Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 50 mcg. Each pink tablet in Demulen 1/50-28 is a placebo containing inert ingredients. **Indication and usage:** For prevention of pregnancy. Pregnancy rate for products with ≥35 mcg ethinyl estradiol or ≥50 mcg mestranol is ≤1/100 woman-years. With ≤35 mcg ethinyl estradiol, rate is slightly higher; with progestogen-only oral contraceptives (OCs), rate is about 3. Precise comparisons cannot be made. Rates for other methods have been published. *Dose-related Thromboembolic Risk*: Studies showed positive association between OC estrogen dose and thromboembolic risk. It is in keeping with good therapeutics to minimize estrogen exposure. Prescribe product containing least amount of estrogen compatible with acceptable pregnancy rate and patient acceptance. Start new users on ≤50 mcg estrogen. **Contraindications:** Thrombophlebitis, thromboembolic disorders, past history of deep vein thrombophlebitis or thromboembolic disorders; cerebrovascular disease, myocardial infarction or coronary artery disease, or past history of these; known or suspected breast carcinoma, estrogen-dependent neoplasia, or pregnancy; undiagnosed abnormal genital bleeding; past or present, benign or malignant liver tumors developing during use of estrogenic products. **Warnings:**

Cigarette-smoking increases risk of serious cardiovascular side effects from OC use. Risk increases with age and heavy smoking (15 or more cigarettes/day) and is quite marked in women over 35. OC users should be strongly advised not to smoke. OCs are associated with increased risk of several serious conditions including venous and arterial thromboembolism, thrombotic and hemorrhagic stroke, myocardial infarction, visual disorders, hepatic tumors, gallbladder disease, hypertension, fetal abnormalities. Practitioners should be familiar with the available information relating to these and other risks.

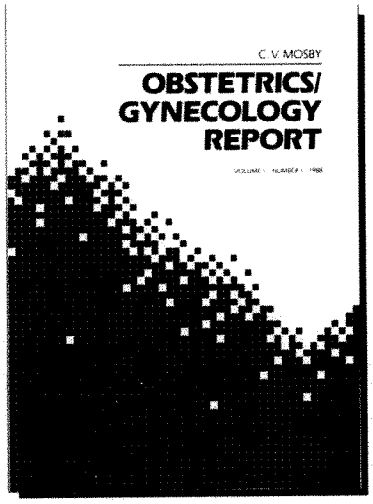
1. *Thromboembolic disorders and other vascular problems:* Increased risk of thromboembolic and thrombotic disease associated with OCs is well established. A British study showed increased risk for fatal venous thromboembolism (TE). British and U.S. studies showed increased risk for nonfatal disease. U.S. studies showed increased risk for stroke. OC users were 2-11 times more likely to manifest these diseases without evident cause. In a study of idiopathic deep vein thrombosis and pulmonary embolism (PE), projected hospitalization rates for ages 16-40 were 47/year/100,000 users and 5 for nonusers. Overall excess mortality from PE or stroke was 1.3-3.4 deaths/year/100,000 users and increased with age. *Cerebrovascular Disorders:* In a study of stroke with and without predispositions, risk of hemorrhagic stroke was 2 times greater and thrombotic stroke 4.0-9.5 times greater in users. Mortality trends in 21 countries indicate that changes in cardiovascular mortality were associated with changes in OC prevalence. The Royal College of GPs (RCGP) reported on its prospective study: "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." A 1981 analysis showed a 4-fold increased mortality in users from circulatory diseases, mainly myocardial infarction (MI) and hemorrhagic stroke. Excess mortality was associated with age and smoking. A 1983 analysis showed elevated cerebrovascular disease, increasing with use to 8 yrs, including cerebral thrombosis or embolism and TIA. Peripheral arterial disease and MI were increased. Women over 30 had more arterial disease, being greatest in smokers. Arterial case-fatality was 2-3 times greater for users who smoked. Family Planning Assoc. (FPA) found significant association between OC use and stroke; increased risk for venous thrombosis and PE was 4-fold and statistically significant. Mortality from nonrheumatic heart disease was greater in ever-users. In the Walnut Creek Study, subarachnoid hemorrhage risk was associated with smoking, age, and OC use. *Myocardial Infarction:* Increased risk of MI associated with OCs was reported in Britain, as previously suspected. The morbidity study found the greater the number of risk factors for coronary artery disease (smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk, regardless of OC use. OCs were an additional risk factor. Excess rate of fatal MI was 3.5/year/100,000 users aged 30-39 and 20 for ages 40-44. (These are based on British statistics with acute MI death rates 2-3 times less than the U.S. Similar estimates for the U.S. are 25.7 for users aged 30-39 with predispositions vs 1.5 without; for ages 40-44, 86.2 vs 5.1.) Excess hospitalization rate for nonfatal MI in Britain was 3.5/year/100,000 users aged 30-39 and 47 for ages 40-44. Smoking major predisposing condition to MI. In terms of relative risk, nonsmoking OC users are twice as likely to have fatal MI as nonsmoking nonusers. Smoking users have a 5-fold greater risk than nonsmoking users, but a 10-12-fold greater risk than nonsmoking nonusers. Amount of smoking is an important factor. In determining importance of these risks, give serious consideration to rates in table below. Importance of other predispositions cited above in determining relative and absolute risks has not been quantified; it is likely the same synergism exists, but perhaps to a lesser extent. U.S. studies similarly relate MI, OCs, smoking, and age.

Estimated Mortality Rate from Myocardial Infarction per 100,000 Women/Year

	Aged 30-39:	*Users*	*Nonusers*	*Aged 40-44:*	*Users*	*Nonusers*
All smokers		10.2	2.6		62.0	15.9
≥15 cigarettes daily		13.0	5.1		78.7	31.3
<15 cigarettes daily		4.7	0.9		28.6	5.7
Nonsmokers		1.8	1.2		10.7	7.4
Smokers and nonsmokers		5.4	1.9		32.8	11.7

Risk of Dose: Reports of TE after use of OCs with ≥50 mcg estrogen received by drug safety committees in Britain, Sweden, and Denmark were compared with distribution expected from market research sales estimates. A positive correlation was found between estrogen dose and reporting of TE, including coronary thrombosis, in excess of that predicted by sales. OCs with ≥100 mcg estrogen were associated with higher TE risk than those with 50-80 mcg. Estrogen quantity may not be the sole factor; influence of progestogens was not considered, which may be responsible for certain discrepancies in the data. No significant differences were noted between OCs containing same estrogen dose nor between ethinyl estradiol and mestranol. In Britain certain TE conditions were associated with progestogen or estrogen dose. In Sweden reports of TE decreased when higher estrogen doses were no longer prescribed. Studies on TE risk with progestogen-only OCs have not been done. Cases have been reported for these; they are not presumed free of risk. In a U.S. case-controlled study, relative risk of OC use 1 month before hospitalization for various types of TE was calculated. If relative estrogenic potency and possible influence of different progestogens are ignored, OCs may be divided into those with <100 mcg and those with ≥100 mcg estrogen. For all cases combined, larger doses were associated with only slightly higher risk; for idiopathic cases risk was doubled with larger doses, but confidence limits overlapped and differences were not significant. Apparently there was less increased risk for cases with predispositions. In FPA study no nonhemorrhagic strokes occurred with <50 mcg estrogen, vs 13 with higher doses. TE risk in users and nonusers increases with age. OCs have been considered an independent risk factor. *Persistence of Risk* after OC discontinuation was reported for circulatory disease, nonrheumatic heart disease, and cerebrovascular disease, including subarachnoid hemorrhage, cerebral thrombosis, and TIA. *Excess Mortality from Circulatory Diseases:* A U.K. prospective study estimated annual mortality from circulatory diseases for OC users and nonusers by age, smoking, and duration of use. Excess mortality was 23/100,000 users (2 and 10 for ages 25-34, 15 and 48 for ages 35-44, 41 and 179 for ages >44, for nonsmokers and smokers, respectively). Risk was significant only for smokers over 34. Most deaths were due to subarachnoid hemorrhage or ischemic heart disease. Risk for ever-users rose with parity. One study estimated risk of death with various contraceptive methods, each estimate including risk of method (eg, TE for OCs) plus risk due to pregnancy or abortion in cases of method failure. This latter risk varies with effectiveness. It concluded mortality with all methods is low and below that of childbirth, except for OC users over 40 who smoke. Heavy smokers have double the risk of smokers, light smokers about half. Mortality with OC use in nonsmokers over 40 is higher than with any other method in that age group. Lowest mortality is with condom or diaphragm backed up by early abortion. Risk of TE and thrombotic disease with OCs increases with age after 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia, and especially cigarette smoking. Based on current data, the chart gives gross estimates of risk of death from circulatory disorders associated with OCs:

Risk is: A—very high; B—high; C—moderate; D—low.	Age:	<30	30-39	≥40
Heavy smokers (≥15/day)		C	B	A
Light smokers (<15/day)		D	C	B
Nonsmokers, no predispositions		D	C,D	C
Nonsmokers, with predispositions		C	C,B	B,A



Be alert to earliest manifestations of TE and thrombotic disorders (eg, thrombophlebitis, PE, cerebrovascular insufficiency, coronary artery disease, MI, retinal thrombosis, mesenteric thrombosis). Should any be suspected, discontinue OCs immediately. A 4-7-fold increased risk of postsurgery TE was reported in users; if feasible discontinue OCs at least 4 weeks before surgery or in prolonged immobilization. Before resuming OCs, weigh risks of postsurgery TE complications against contraceptive needs. The RCGP prospective study reported higher incidence of superficial and deep vein thrombosis in users, the former correlated with progestogen dose. The data suggest varicose veins have little effect on development of deep vein thrombosis but substantially increase risk of superficial vein thrombosis, risk depending on severity of varicosities. **2.** *Ocular lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OCs. Discontinue if there is unexplained, gradual or sudden, partial or complete loss of vision; proptosis or diplopia; papilledema; or evidence of retinal vascular lesions. Institute diagnostic and therapeutic measures. **3.** *Carcinoma:* Long-term estrogen in certain animals increases carcinomas and/or nonmalignant neoplasms, such as those of breast, uterus, cervix, vagina, ovary, liver, pituitary. Some synthetic progestogens, none currently in OCs, increase incidence of benign and malignant mammary nodules in dogs. There is evidence that estrogens increase risk of human endometrial carcinoma. In case-controlled studies, increased risk (2.2-13.9 times) associated endometrial carcinoma with prolonged estrogen for menopausal symptoms. Risk was independent of other known risk factors and depended on duration of use and dose. This is supported by increased endometrial cancer incidence since 1969 in areas with cancer-reporting systems, which may be related to rapidly expanding estrogen use. There is no evidence that natural estrogens are more or less hazardous than synthetics at equi-estrogenic doses. Of the first 30 cases of endometrial carcinoma in OC users under 40, those without predispositions (eg, irregular bleeding before OCs, polycystic ovaries) occurred nearly always with no-longer-marketed sequential OCs. No statistical association is reported suggesting increased endometrial cancer with combination or progestogen-only OCs, though individual cases were reported. Studies show no increased breast cancer with OCs or estrogens. However, greater risk was noted in OC users with benign breast disease or long-term (2-4 years) use. One study found greater risk of breast cancer with >4 years OC use prior to first full-term pregnancy. Risk of breast cancer with menopausal estrogens rose and further increased with duration of follow-up. OCs or estrogen were related to breast cancer in connection with other risk factors. Decrease in benign breast tumors in OC users is well known. Some studies suggested increased risk of cervical dysplasia, erosion, and carcinoma in long-term users. Cervical microglandular hyperplasia has been reported. In summary, there is no consistent evidence from human studies of increased cancer risk with OCs. Close surveillance is, however, essential. In undiagnosed persistent or recurrent abnormal vaginal bleeding, consider nonfunctional causes and take diagnostic measures to rule out malignancy. Carefully monitor users with strong family history of breast cancer or with breast nodules, fibrocystic disease, recurrent cystic mastitis, abnormal mammograms, or cervical dysplasia. **4.** *Hepatic adenomas, etc* have been associated with OCs. In 1 study OC formulations with high "hormonal potency" were associated with higher risk, as was age over 30. Though benign, these lesions may rupture and cause fatal hemoperitoneum in short- or long-term users. Two studies related risk to duration of use, being much greater after ≥4 years. Long-term OC users have an estimated adenoma incidence of 3-4/year/100,000. Consider such lesions in users with abdominal pain, tenderness, mass, or shock. About 25% present with abdominal masses, up to half with acute hemoperitoneum. Radiologic and lab studies may not be helpful; liver scans may show local defect. Hepatic arteriography or CAT may be useful. Hepatocellular carcinoma risk is increased 7-20 times in users for 8 or more years. Bile duct cancer may occur with OC use. OCs are contraindicated in case of past or present, benign or malignant liver tumors developing during use of estrogenic products. **5.** *Use in or immediately preceding pregnancy, birth defects, malignancy in offspring:* Estrogens or progestogens during early pregnancy may seriously damage offspring. Females exposed in utero to DES and other nonsteroidal estrogens may have increased risk of vaginal or cervical cancer. Though OCs may not enhance this risk, monitor such patients carefully. From 30-90% of DES-exposed women develop benign vaginal or cervical adenosis, which could be premalignant. DES-exposed daughters have more unfavorable pregnancy outcomes. Males so exposed may develop urogenital and sperm defects. Other estrogens may mimic DES. Reports relate fetal exposure to female sex hormones and congenital anomalies, eg, VACTERL for vertebral, anal, cardiac, tracheoesophageal, renal, and limb defects. There appears preferential expression by males. There was a 4.7-fold increased risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal pregnancy tests, or treatment for threatened abortion). Some exposures were very short, being only a few days. Cardiovascular defects in children exposed to female hormones, including OCs, during early pregnancy occurred in 18.2/1,000 births, compared to 7.8 for those unexposed (P<.05). More twinning was reported in conceptions shortly after OC discontinuance. Female sex hormones were used for threatened or habitual abortion, but there is considerable evidence estrogens are ineffective and no evidence progestogens are effective. Triploidy and possibly other polyploidy may be increased in abortuses from women becoming pregnant soon post-OC. These almost always abort spontaneously. It is unknown if spontaneous abortion is increased soon after stopping OCs. Increased chromosome aberrations have been reported. Safety of OCs in pregnancy has not been demonstrated. Rule out pregnancy in using OCs and always consider it if withdrawal bleeding does not occur. If 2 consecutive periods are missed rule out pregnancy before continuing. If user deviates from regimen, consider pregnancy at first missed period and withhold OCs. If pregnancy is confirmed, apprise patient of potential fetal risks and discuss continuation of pregnancy. Users discontinuing for pregnancy should use alternative contraception for 3 months before attempting to conceive, though this is not based on precise information. Do not use progestogen-only or progestogen-estrogen drugs as pregnancy tests. **6.** *Gallbladder disease* risk, surgically confirmed, appeared after 2 years' use and doubled after 4-5 years in 1 study; it appeared in 6-12 months' use in another. **7.** *Carbohydrate and lipid metabolism:* Decreased glucose tolerance occurs in a significant number of users; carefully observe diabetic and prediabetic patients. Triglycerides, total phospholipids, and lipoproteins may increase. **8.** *Elevated blood pressure* (BP) occurs in some users in a few months, and degree may relate to progestogen dose. Hypertension prevalence in users is not higher in the first year, but increases with longer exposure; in the 5th year it is 2½—3 times the first year. Age is strongly correlated with hypertension in users. Those with history of elevated BP (hypertension), preexisting renal disease, history of toxemia or elevated BP in pregnancy, familial tendency to hypertension or its consequences, or history of excessive weight gain or fluid retention during menstrual cycles may be more likely to develop elevated BP on OCs and should be monitored closely. Even though elevated BP may be in "normal" range, do not ignore implications. Follow closely, particularly those with other risk factors for cardiovascular disease or stroke. High BP may or may not persist after stopping OCs. **9.** *Headache:* Onset or exacerbation of migraine or development of headache of a new pattern that is recurrent, persistent, or severe requires stopping OCs and evaluating cause. **10.** *Bleeding irregularities:* Breakthrough bleeding (BTB), spotting, and amenorrhea are frequent reasons for discontinuing. In BTB, as in all cases of irregular bleeding, consider nonfunctional causes. In undiagnosed persistent or recurrent bleeding, rule out pregnancy or malignancy. If pathology is excluded, time or change to another product may suffice. Change to a higher-estrogen OC only when necessary as this may increase thromboembolic risk. Those with history of oligomenorrhea or secondary amenorrhea or without established regular cycles may be anovulatory or amenorrheic after discontinuing. Those with such problems should be so informed and other methods encouraged. Post-use anovulation, possibly prolonged, may occur in women without previous irregularities. Higher incidence of galactorrhea and of pituitary tumors has been associated with postpill amenorrhea. One study reported 16-fold increased prevalence of pituitary prolactin-secreting tumors in patients with postpill amenorrhea when galactorrhea was present. **11.** *Ectopics:* In failures with combination OCs, the ratio of ectopic to intrauterine pregnancies is no higher than in nonusers. There may be increased risk of ectopics after discontinuing. **12.** *Breast feeding:* OCs may decrease quantity and quality of milk. A small fraction of OC steroids appears in milk. Effects if any on child are unknown. If feasible defer OCs until after weaning. **13.** *Infertility* may occur after discontinuing OCs. While impairment diminishes with time, there is still an appreciable difference in nulliparas aged 25-29 after 30 months; difference is negligible after 48 months. In nullips aged 30-34 impairment persists to 72 months and is more severe for 2-year users. In paras aged 25-34, difference is negligible after 30 months. **Precautions:** Conduct complete history and physical prior to OC use and annually thereafter. Include breasts, abdomen, and pelvis, with BP, Pap, and lab tests. Preexisting uterine leiomyomata may enlarge. Mental depression may occur; with positive history, observe carefully and discontinue if serious recurrence. Fluid retention may occur; prescribe cautiously and monitor carefully in convulsive disorders, migraine, asthma, or cardiac, hepatic, or renal dysfunction. History of jaundice in pregnancy increases risk of recurrence on OCs; observe carefully and discontinue if it occurs. Cholestatic jaundice occurred after OC and troleandomycin use. OC/cyclosporine combination may be hepatotoxic. Steroids may be poorly metabolized in liver dysfunction and should be given cautiously. Tryptophan metabolism may be disturbed and result in pyridoxine deficiency; megaloblastic anemia has been reported. Serum folate may be depressed and may be exacerbated in post-OC pregnancy. Advise pathologist of OC use when submitting specimens. Endocrine and liver function tests may be altered; repeat abnormal tests after stopping for 2 months. These have been observed: increased BSP retention and other abnormalities in liver function tests; increased prothrombin and coagulation factors VII, VIII, IX, X; decreased antithrombin III, increased platelet aggregability; increased thyroid-binding globulin leading to increased circulating total thyroid hormone (PBI, T^4); decreased T^3 uptake, unaltered free T^4, decreased pregnanediol excretion; reduced metyrapone response; increased blood transcortin, corticosteroid, triglyceride, phospholipid, reduced serum folate; impaired glucose tolerance; altered plasma trace minerals. Influence of prolonged OC use on pituitary, ovarian, adrenal, hepatic, or uterine function, or on immune response not established. OCs may mask onset of climacteric. Cervical chlamydial prevalence is increased; do not assume OC protects against chlamydial PID. *Information for patients.* See patient labeling. *Drug interactions:* OC effectiveness may be decreased and more BTB occur with rifampin, isoniazid, ampicillin, neomycin, penicillin V, tetracycline, chloramphenicol, sulfonamides, nitrofurantoin, griseofulvin, barbiturates, phenytoin, carbamazepine, primidone, phenylbutazone, analgesics, tranquilizers, antimigraines. OCs may alter effectiveness of oral anticoagulants, anticonvulsants, tranquilizers, tricyclic antidepressants, antihypertensives, theophylline, caffeine, vitamins, hypoglycemics, clofibrate, glucocorticoids, acetaminophen. **Adverse reactions:** Increased risk of the following serious adverse reactions has been associated with OCs: thrombophlebitis and thrombosis; pulmonary embolism; arterial thromboembolism; Raynaud's disease, myocardial infarction; coronary thrombosis; cerebral thrombosis; cerebral hemorrhage; hypertension; gallbladder disease; Budd-Chiari syndrome; benign adenomas and other hepatic lesions, with or without intra-abdominal bleeding, liver cancer, congenital abnormalities. There is evidence of association between the following and OCs, though confirmatory studies have not been done: mesenteric thrombosis; neuro-ocular lesions, eg, retinal thrombosis and optic neuritis. The following are believed drug related: nausea, vomiting, gastrointestinal symptoms, BTB, spotting, change in menstrual flow, dysmenorrhea, amenorrhea during and after use, infertility post-OC, edema, chloasma or melasma, which may persist post-OC, breast changes (tenderness, enlargement, secretion), weight changes, change in cervical erosion and secretion, endocervical hyperplasia, lactation decrease, cholestatic jaundice, migraine, enlarged uterine leiomyomata, allergic rash, mental depression, reduced carbohydrate tolerance, vaginal candidiasis, change in corneal curvature (steepening), intolerance to contact lenses. Association not confirmed or refuted for: premenstrual-like syndrome, cataracts, libido changes, chorea, appetite changes, cystitis-like syndrome, headache, paresthesia, nervousness, dizziness, auditory disturbances, rhinitis, fatigue, backache, hirsutism, scalp hair loss, erythema multiforme or nodosum, hemorrhagic eruption, herpes gestationis, hemolytic uremia, malignant hypertension, itching, vaginitis, porphyria, impaired renal function, acute renal failure, sometimes irreversible, PVCs, abnormal EKG, pulmonary hypertension, TTP, anemia, pancreatitis, hepatitis, colitis, Crohn's disease, gingivitis, dry socket, lupus erythematosus, rheumatoid arthritis, pituitary tumors (eg, adenoma) with amenorrhea and/or galactorrhea after use, malignant melanoma, endometrial, cervical, breast, and bile duct carcinoma. **Acute overdosage:** Serious ill effects have not been reported after large acute doses of OCs in young children. Nausea and withdrawal bleeding might occur. **Important note: Complete prescribing information should be consulted prior to use and is available on request.**

An idea whose time has come

OBSTETRICS/GYNECOLOGY REPORT

The depth of texts, the timeliness of journals . . .

OBSTETRICS/GYNECOLOGY REPORT, a **new** resource that works for **you**, is a synthesis of current information on the most important clinical developments in the field. The REPORT makes it **convenient** for the busy practitioner to stay up to date.

- Three issues every 12 months.
- Each issue focuses on two main topics within the specialty:

Vol. 1, No. 1	Infectious diseases Reproductive endo-fertility
Vol. 1, No. 2	Fetal monitoring Human papilloma virus
Vol. 1, No. 3	Breast disease Urinary incontinence

- Comprehensive coverage of the selected topics, from new developments to cases of interest.
- Approximately 150 pages per issue; no advertisements.
- Attractive, two-color format throughout.

Our editorial board of prominent physicians is committed to offering you an insightful, reliable, and practical resource that truly is beneficial to clinical practice.

vaginal cream 2%
Femstat® Prefill
(butoconazole nitrate)

BRIEF SUMMARY

INDICATIONS: FEMSTAT® (butoconazole nitrate) vaginal cream 2.0% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS: FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS: General: If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient: Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis: Animal studies have not been done.

Mutagenesis: Mutagenicity studies were negative.

Impairment of Fertility: Animal studies showed no impairment of fertility.

Pregnancy Category C: Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers: Use with caution.

Pediatric Use: Safety and efficacy have not been established.

ADVERSE REACTIONS: Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION:
Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

Your comprehensive reference guide to a decade of valuable clinical information . . .

Ten-Year Cumulative Index (1978-1987) to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

Now you have easy access to 10 years of clinical information, indexed in one convenient source — the Ten-Year Cumulative Index to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY.

This hard-cover index is a comprehensive guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the Journal from 1978 through 1987 (volumes 130 to 157). These influential, peer-reviewed papers are indexed both by subject and by author.

The Cumulative Index features:
- more than 800 pages
- both a subject and an author index
- 4,331 subject headings, containing 24,126 references
- 22,456 author entries

The Cumulative Index is a great time-saver for locating information on clinical topics of immediate or historical significance in obstetrics and gynecology. There's no need to search for index issues from each year.

Order this key reference guide for your personal library!

Heuristic determination of relevant diagnostic procedures in a medical expert system for gynecology

Steven L. Small, PhD,[a] and Eberhard K. Muechler, MD[b]

Pittsburgh, Pennsylvania, and Rochester, New York

Many professions including medicine have standard operating procedures for the performance of their tasks. In the construction of expert systems, knowledge engineers have exploited this fact in devising heuristic rules that mimic the standard practice among such personnel (i.e., experts). This article suggests that the expert system designer should not stop at the level of the standard operating procedure heuristic but should instead investigate the reasons that the standard procedures have become standard. Because the experts in a field often do not understand the reasons for the standard operating procedures of their profession, this effort not only rewards the system designer but the expert as well. Because medical training does not always emphasize the logical reasoning underlying certain standard operating procedures, the ability to perform this reasoning is especially important in medicine. Further, a medical expert system for consultation or education would make a valuable impact by incorporating such knowledge and inference rules. This article investigates the development of a computerized medical expert system that applies the principles of artificial intelligence by limiting the number of questions and tests to find the solution for an ill-defined complex problem. Finally, we describe a logic program that tests the basic ideas. (Am J Obstet Gynecol 1989;161:17-24.)

Key words: Artificial intelligence, medical expert system, diagnostic reasoning in gynecology

The purposes for building expert systems in medicine are either (1) clinical advice for physicians who are experts or nonexperts in the particular area of the program, or (2) teaching students or postdoctoral trainees of the methods of practice in that area. Because these systems may reflect accurately the long-standing methods of medical education and practice in their emphasis on standard operating procedures, perhaps the use of automated reasoning could be used to improve this practice. Both consultation and educational programs might be substantially improved by more extensive reasoning than can be obtained by the typical standard operating procedure (SOP) heuristics of these systems.

Existing medical expert systems that are aimed at the diagnostic instead of the treatment phase seem to use variations on two similar approaches: (a) the findings/diagnosis matrix and (b) the findings/conclusion rule set. Most of the type a systems do not represent causality in any direct way and instead rely on correlations between sets of findings and conclusions. Usually they are not considered to be artificial intelligence systems, but their designers do call them expert systems. Our attention was called to this approach by a large system to diagnose problems of infertility in couples.[1] The system scored a wide range of findings and attempted to rule in and rule out diagnoses from a large number included in the data base. The type b systems (artificial intelligence medical (AIM) systems) represent causality directly, and the different chains of reasoning from the given findings to the possible conclusions are scored by their likelihood of being correct. The likelihood for any chain of reasoning depends on numerical combination of the individual likelihoods for each reasoning step. In both type a and type b systems, the scoring systems are applications of mathematical physics. A group of abstract speculations are written as equations in a computer program and the computer solves the equations by using a numerical value system for reaching conclusions.

These medical expert systems incorporate vast amounts of knowledge centered on the different medical findings and the conclusions that can be drawn from these findings. However, in actual practice the availability of different findings depends on the physician's ability to ask the proper questions, perform procedures; or request that procedures be performed. Furthermore, the physician is expected to perform the required diagnostic procedures in some rational order and to perform only those procedures that are actually required to make the correct diagnosis. This situation suggests that the diagnostic procedures themselves be given a focal place in the representation of medical knowledge for diagnosis. The gynecologic domain of infertility is used in this presentation. It represents a well-defined field with medical experts (reproductive

From the Department of Computer Science and the Decision Systems Laboratory, University of Pittsburgh,[a] and the Department of Obstetrics and Gynecology, University of Rochester.[b]

endocrinologists) who daily perform the complex tasks of decision making with patients and teach patterns of abstract thinking to students and residents.

The system to be described uses knowledge about diagnostic procedures as a fundamental source of heuristic knowledge for problem solving. Thus it broadens the search space from the space of diagnostic findings to one that includes the examinations and tests that obtain those findings. The heuristic rules weigh the advantages and disadvantages of different procedures at each stage of the search for an accurate diagnosis.

Heuristics are strategies (rules of thumb) that are applied to a defined set of observations that are obtained by patient history, physical findings, and laboratory tests assigned a value system to reach conclusions and recommendations. Artificial intelligence uses heuristics in computer programs to mimic the ability to solve problems by medical experts. In cases of female infertility the most relevant facts in the history focus on the menstrual cycle, a history of pain, infection, contraceptive use, and previous pelvic surgery. The observations of physical examination are usually confined to a limited set of findings obtained by inspection and palpation, such as appearance and color of the cervix and vagina; size, position, and regularity of uterus, ovaries, and tubes; presence or absence of pain on palpation, change in consistency of structures that are usually not palpable (ligaments). In addition to this information, a set of biochemical laboratory procedures (e.g., blood count, blood chemistry, and hormone values) and biophysical tests (e.g., ultrasonography, hysterosalpingogram, endometrial biopsy, hysteroscopy, and laparoscopy) define the process of data gathering that leads the medical expert to conclusions and decisions. The cost factor of different procedures is subconsciously incorporated by medical experts in assigning a rank order in the decision-making process. Note that "cost" is defined in the most general sense of the word, including morbidity and mortality as the most important costs, with pain, inconvenience, and financial factors as secondary costs. However, the financial cost of a procedure itself implicitly represents to some extent the overall risk factor of the procedure.

Diagnostic procedure reasoning

Our goal has been to explore the diagnostic process to construct a computer program that can reason over a range of gynecologic problems. Diagnostic process is defined as the step-by-step procedure of recommending diagnostic tests and acting on their results. This cycle continues until some test gives a definitive result. Performing the tests themselves is considered adjunctive to the diagnosis process, and is left to the laboratory or physician. The medical problems included in the study are meant to be indicative of typical gynecologic presentations and should not be considered special in any way. If the notions presented do not seem applicable to domains other than the sample domain, then we have not been successful in our approach.

A major decision in the approach to this problem concerned what information was to be given explicitly to the program and what information the program should infer for itself. This issue was confronted early, since a first diagnostic test is recommended for almost all gynecologic patients in almost all circumstances—the pelvic examination. Most gynecologists would claim that this test should always be done as part of an initial patient examination, regardless of the other aspects of this examination. It seemed to us that despite the widespread agreement on the need for this examination as an initial diagnostic procedure, the reasons should be investigated more carefully. If some test seems universally accepted as a standard part of some diagnostic sequence, it must have some specific value in that role, underlying its acceptance, that can be uncovered.

It should be noted that this reasoning is not specific to the pelvic examination or to gynecologic diagnosis. An analysis of the medical history section of the normal physical examination leads to the same questions. Why does the physician take a patient history before performing an exploratory laparotomy when a patient is initially seen with abdominal pain? Likewise, when a computer goes down, why does the system programmer examine the programs that were running on the machine, instead of immediately changing some of the circuit boards? Clearly, the expert medical doctor or computer fault diagnostician considers various costs, such as financial cost or the amount of time required, in a stepwise approach to solving the problem. If a low-cost approach does not succeed, then a higher cost approach should be tried.

Because standard operating procedures exist for troubleshooting in expert domains, and these can be used heuristically in computer programs to advise troubleshooters, it might be advantageous to investigate these procedures and determine why they were initially devised. With that knowledge, a much better expert computer program can be built that incorporates an ability to reason at a deeper level than one based on SOPs. In a system for medical diagnosis, such an approach would lead the designer to consider various levels of explanation back to the relevant physiology and cell biology. The simple medical diagnosis program described in this paper uses information at only a single level removed from normal clinical SOPs. However, for a system to be useful it must be fluent in the more basic explanations.

Instead of focusing exclusively on the causal relationships that pertain in a collection of diagnostic findings, our program uses additional knowledge about the procedures that obtain these findings. It reasons *which* procedures should be performed and *why* they should be performed to obtain the findings that are needed. Thus the course of the overall diagnostic procedure is

driven by the determination of the relevant medical tests or procedures that should be performed at a given point in the process. By making this determination a rational process instead of one based on standard operating procedure, the underlying reasons for performing or not performing a procedure at a particular time, such as cost or effectiveness at evaluating competing diagnoses, can be addressed explicitly. Often these reasons are not even realized explicitly by physicians who make decisions based on them.

The foregoing application of artificial intelligence to gynecology was designed through collaboration between the computer scientist and the medical expert in reproductive endocrinology. In this scenario the medical expert provides the reasoning for abstract decision making and the computer scientist uses mathematical rules of value to arrive at conclusions that simulate the thought process.

As an initial test of these ideas, a small program has been implemented to recommend diagnostic procedures and to use the results of these procedures either to recommend other procedures or to make a final diagnosis. The gynecologic domain in this example consists of the common symptoms of pelvic pain and infertility. The medical expert and the computer should arrive at a limited number of tests and procedures in a logical sequence without excessive cost. The program has been coded in a Horne clause theorem proving system based on Prolog[2] and implemented in Lisp.[2,3]

For each diagnostic procedure the system incorporates a number of facts describing the different classes of findings that that procedure can be used to determine. The following predicate states that the pelvic examination can be used to determine the position of a patient's uterus (anteflexed or retroflexed):

(procedure pelvic-exam uterine-position)

In addition, for each procedure the program includes certain information about the different costs associated with that procedure. The following predicate is representative:

(cost pelvic-exam pain small)

This assertion indicates that the pelvic examination has a small amount of pain associated with it. The program uses symbolic descriptions (e.g., small) instead of numerical coefficients in all user predicates, although ad hoc numerical computations do drive the reasoning.

At least four different cost parameters appear to be considered in the process of choosing which diagnostic procedures to perform at a particular point in evaluating a patient: risk of morbidity, financial cost, pain and suffering, and time expenditure. The overall cost of a procedure is a weighted algebraic sum of these individual factors. In different domains and in certain contexts, each of these factors becomes extremely important to decision making in the real world. The *risk of morbidity* might be always considered paramount, but consider a case in which the diagnoses themselves involve tremendous morbidity. *Financial cost* may in some circumstances depend on the wishes of the payer, which may or may not be a patient. *Pain* may rarely be considered by the physician, but depending on the importance of the procedure, may be important for the patient. The *expenditure of time* does not matter much in most diagnoses in gynecology. Consider the time required to analyze arterial oxygen or carbon dioxide, procedures that are important and common in people with respiratory problems, if the patient shows severe respiratory distress and will suffocate without immediate intervention.

The four cost parameters themselves do not direct the decision-making process toward the correct class of procedures, although they do aid in the decision from among a class of procedures that might be appropriate at a given time. Another needed heuristic must correlate the costs with the diagnostic process, represented by the following information: the need for new findings, the procedures that can obtain those findings, and the plausible competing diagnoses at the current point in the overall stage of reasoning. A physician knows which findings would help to differentiate among the leading diagnoses; indeed, this knowledge has been encoded in many good AIM systems.[4-9] The physician also knows which procedures can provide this information or make suggestions about it. With this knowledge, a program should make good decisions.

Results

Our example program contains an oversimplified set of predicates about these issues. For each possible diagnosis, the data base contains predicates about the classes of findings required to make that diagnosis. The following predicate is typical:

(dxneed chronic-PID tubal-patency)

This assertion indicates that the program needs some value for the parameter *tubal-patency* to make a diagnosis of chronic pelvic inflammatory disease associated with infertility. In fact, the heuristics of the program use these data as suggestions; a finding regarding tubal patency would be helpful for the diagnosis but not necessary. As described above, the data base also contains predicates such as the following, which are used as one might expect:

(procedure HSG tubal-patency)

This datum indicates that the tubal patency of a patient can be assessed with the hysterosalpingogram procedure. These two sorts of facts, along with cost information, are used in conjunction with the leading potential diagnoses to choose an appropriate procedure to recommend. The findings and diagnoses are scored by an ad hoc numerical scheme, but certain numerical

Table I. Diagnoses and tests included in the AIM system

Laparoscopy

values (thresholds) are assigned symbolic names for use in the heuristics.

The currently operating computer system comprises approximately 50 rules and approximately 100 basic facts. The relevant diagnoses and tests are listed in Table I. To recommend a diagnostic procedure, the system uses logic to try to "prove" that a certain procedure should be recommended. Each such proof must be based on proving a number of other smaller notions, until eventually a combination of simple facts suffices to complete the picture. The system uses two primary heuristic rules for recommending procedures, both of which will be presented here. Note that each rule calls on the system to perform a number of other tasks (i.e., to prove that a number of conditions pertain) before making the recommendation. These secondary rules are not illustrated here.

The data base of the system stores the names of the procedures that it can recommend, such as the pelvic examination, hysterosalpingogram, or laparoscopy. The system attempts to recommend all of these procedures, and is allowed to use any available rules to do so. However, the resulting recommendation always consists of a single procedure because of the nature of the rules themselves (shown below), which prefers first, useful procedures, and second, ones that are of low cost.

The basic heuristic for recommending a diagnosis consists of the following:

1. Find two diagnoses that are plausible
2. Find one class of findings that are needed by both
3. Find a procedure that can get this finding that has not already been performed, and
4. Ensure that the cost of this procedure is low

A *diagnosis* is considered *plausible* if its score has reached a certain threshold. A diagnosis is considered *suggested* or *probable* if its score has reached one or another higher threshold. A suggested or probable diagnosis warrants a more costly procedure than does a plausible one.

The computer program code for this first heuristic rule illustrates the predicates used and the order in which they are evaluated. The horn clause below contains a conclusion on the left and a conjunction of preconditions on the right:

```
((recommend ?proc) < (diagnosis ?dx1
                      plausible)
                     (diagnosis ?dx2
                      plausible)
                     (NEQ ?dx1 ?dx2)
                     (dxneed ?dx1 ?param)
                     (dxneed ?dx2 ?param)
                     (procedure ?proc
                      ?param)
                     (status procedure ?proc
                      available)
                     (sumcost ?proc ?cost)
                     (maximumthreshold
                      sumcost ?cost minimal))
```

This rule can be written in English as follows:

If: Some diagnosis dx1 is plausible;
and
Some diagnosis dx2 is plausible;
and
Diagnoses dx1 and dx2 are not the same; and
Finding param helps in the diagnosis dx1; and
Finding param helps in the diagnosis of dx2; and
Procedure proc can determine finding param; and
Procedure proc has not yet been performed and
The cost of procedure proc is cost; and
Cost cost is minimal; then

Conclude: Procedure proc is recommended

Currently, a simple polynomial equation computes the cost of a particular procedure and the coefficients for this polynomial are not context dependent. The symbolic name of a cost (e.g., minimal) represents a threshold on a numerical parameter. Note that each of the conditions in the "if" leads to the use of additional rules (e.g., showing that some diagnosis is "plausible"). It is important to understand the reclusive nature of a reasoning system based on logical axioms and proof techniques. In the two heuristic rules shown, a number of additional rules are involved to achieve the goal. For example, rules exist to find competing diagnoses. These particular rules comprise no more than a numerical evidence scheme as in Mycin,[4] with mappings from numbers to labels (e.g., "plausible" or "definitive"). The reclusive algorithm ensures all diagnoses included in the system (see Table I) are exhaustively searched until the diagnoses with the needed attribute (e.g., "plausible") are found.

In using the first heuristic, the system attempts first

to prove that the diagnoses of chronic pelvic inflammatory disease and leiomyoma are plausible. If one of these could not be proved, the system tries reclusively another diagnosis until finding the two needed. In fact, one computational argument against proof-based systems is the slow nature of exhaustive search.

Sometimes a physician bypasses the lowest cost procedures in favor of a procedure of significantly higher cost because of an intuitive feeling that a particular diagnosis can be confirmed. What this probably represents is something that has been incorporated in INTERNIST[6] for some time, namely, that the difference in score between the top two diagnoses may be more important than the absolute score of either.[10] This second main heuristic rule is applied as follows:

1. Find the two highest ranking diagnoses.
2. Make sure their scores are very far apart.
3. Find a class of findings that can make the top diagnosis definitive.
4. Find a procedure that can get this finding.

This situation occasionally occurs in the gynecology domain, when some patient presentation resembles a classic pattern so closely that diagnostic surgery such as laparoscopy is performed immediately without the lower cost pre-procedures that ordinarily precede it. This is illustrated in the sample trace shown in the Appendix, when laparoscopic surgery becomes the procedure of choice early in the diagnostic process because of an overwhelming system preference for one diagnosis (i.e., endometriosis) over all others. Our program performs the same inference that is expected from a medical expert who uses his complex thought process for proceeding with the differential diagnosis and arriving at a specific conclusion that is accurate and cost effective.[11]

The program code for this heuristic rule might be helpful for understanding the nature of the system:

```
((recommend ?proc) < (SETVALUE ?topdx
                      (bestdx 1))
                     (SETVALUE ?seconddx
                      (bestdx 2))
                     (dxvalue ?topdx ?topval)
                     (dxvalue ?seconddx
                      ?secondval)
                     (freqcode spread large
                      ?spread)
                     (spreaddx ?topval
                      ?secondval ?spread)
                     (dxneed ?topdx ?param)
                     (finding ?param ?topdx
                      definitive)
                     (procedure ?proc
                      ?param)
                     (status procedure ?proc
                      available))
```

This rule could be written in English as follows:

If: Some diagnosis topdx is currently the best; and
Some diagnosis seconddx is currently second; and
Diagnosis topdx has value topval; and
Diagnosis seconddx has value secondval; and
Diagnosis values differing by at least spread are far apart; and
The topval and secondval differ by more than spread; and
Finding param is needed to diagnose topdx; and
Finding param can make topdx definitive; and
Procedure proc determines finding param; and
Procedure proc has not yet been performed; then
Conclude: Procedure proc is recommended

The computer program trace in the Appendix illustrates the application of both this rule and the preceding one in a diagnostic problem.

Comment

Standard operating procedures are used in medicine to enable an economy of memory in medical experts. Because such economy may be necessary because of the vastness of medical knowledge, the construction of expert systems may aid the physician in organizing and presenting this knowledge. The construction of expert systems may aid the physician in organizing and presenting this knowledge. The expert system should incorporate the knowledge underlying the heuristic SOPs of the physician in addition to the higher level consolidated rules. One such form of knowledge concerns the risks and costs of diagnostic procedures, which underlie the standard sequences of medical tests involved in deciding diagnoses. Another concerns the physiologic mechanisms that different procedures aim to uncover. All of this knowledge, some of which is not readily at the hands of medical experts, needs to be incorporated in AIM systems.

Appendix: A program trace

This trace shows the application of the two rules illustrated in the body of the paper. First, the program recommends a diagnostic test by applying the rule that suggests low-cost tests to discriminate among plausible examinations in suggesting diagnostic surgery because of the rule that permits the attempt to verify diagnoses that appear to be far more pausible than that of the others. Thus in the second case, the system does not follow the standard operating procedure, which would recommend a procedure to test the patency of the fallopian tubes (HSG) before attempting to validate the principal hypothesis (endometriosis) at greater cost.

    (q-2) (maximum threshold sumcost 7.1 minimal)
    r-2 (maximum threshold sumcost 7.1 minimal)
  (r-1) (recommend pelvic exam)
((recommend pelvic exam))
```

Try to recommend the next step. The system employs the first heuristic rule listed above. Note that a "q" is an attempt to prove something, and an "r" is the successful result. Thus in trying to show that some diagnosis (called dx19) is plausible leads to the successful result that indeed endometriosis is plausible (henceforth, dx19 = endometriosis). The same occurs again with result that dx29 = chronic PID. To show that someone has endometriosis requires the histologic report of ectopic endometrium (parameter 9 = serosal-surface-spot-histology). To show chronic pelvic inflammatory disease requires showing tenderness to the uterus. Since the pelvic exam has not been done, and since it has low cost (the lowest in all categories), it is recommended.

    (r-2) (SETVALUE endometriosis (bestdx 2))
    (q-2) (SETVALUE ?seconddx 1 (bestdx 2))
    (r-2) (SETVALUE chronic-PID (bestdx 2))
    (q-2) (dxvalue endometriosis ?topval 1)
    (r-2) (dxvalue endometriosis 46)
    (q-2) (dxvalue chronic-PID ?secondval 1)
    (r-2) (dxvalue chronic-PID 20)
    (q-2) (freqcode spread large ?spread 1)
    (r-2) (freqcode spread large 24)
    (q-2) (spreaddx 46 20 24)
    (r-2) (spreaddx 46 20 24)
    (q-2) (dxneed endometriosis ?param 1)
    (r-2) (dxneed endometriosis s-s-spot-histology)
    (q-2) (finding s-s-spot-histology endometriosis definitive)
    (r-2) (finding s-s-spot-histology endometriosis definitive)
    (q-2) (procedure ?x s-s-spot-histology)
    (r-2) (procedure laparoscopy s-s-spot-histology)
    (q-2) (status procedure laparoscopy available)
    (r-2) (status procedure laparoscopy available)
    (r-1) (recommend laparoscopy)
  ((recommend laparoscopy))
```

Here the system employs the other main heuristic rule of the system. It tries to find the two diagnoses with the top scores. Since their scores differ by a substantial margin, the system does not recommend the procedure with the lowest cost, but instead recommends the procedure that will be definitive in affirming the highest ranked diagnosis (or in ruling it out). To obtain histology of "serosal surface spots" requires laparoscopy. Thus the system can prefer a higher cost procedure if the benefits (finding the answer) are great enough.

Breech presentation after cesarean section: Always a section?

Ella Ophir, MD, Moshe Oettinger, MD, Arie Yagoda, MD, Yacov Markovits, MD, Nathan Rojansky, MD, and Harry Shapiro, MD

Nahariya, Israel

A retrospective review of 71 breech deliveries after previous cesarean was done to determine the need for repeat cesarean section. Twenty-four (33.8%) women were allocated to the elective repeat cesarean section group and forty-seven (66.2%) patients were allocated to a trial of labor group. Thirty-seven (78.7%) were delivered of their infants vaginally. A total of 37 of the 71 women (52.1%) had successful vaginal deliveries. Neonatal morbidity did not differ for women who were delivered vaginally or by cesarean section. Maternal febrile morbidity was significantly higher in the cesarean section group than in the vaginal delivery group ($p < 0.001$). On the basis of these data, a trial of labor seems reasonable in carefully selected cases of breech presentation after a previous cesarean section. (Am J Obstet Gynecol 1989;161:25-8.)

Key words: Breech presentation, previous cesarean section, trial of labor

The optimal mode of delivery for a breech pregnancy has remained a subject of controversy. The first prospective report in 1978 concluded that it seems reasonable to allow vaginal delivery in carefully selected cases of term frank breech presentations.[1] Many other investigators have contributed to the overall improvement in outcome in breech labor and delivery.[2-4] The summation of these principles into a single protocol has resulted in a modern approach to the breech fetus.

For patients who arrive in labor with a breech presentation and have a scarred uterus from a previous cesarean section, the consensus is that the patient should have a repeat cesarean section.[5] However, this point of view is not supported by an abundance of data and may change in the future. The purpose of our report is to present our experience in allowing women with breech presentation after previous cesarean section a trial of labor.

Material and methods

During the 11-year inclusive period between 1977 and 1987, there were 43,396 deliveries; 78 deliveries were with singleton breech presentation after previous cesarean section in 32 to 42 weeks of pregnancy. It has been our policy since 1977 to offer a trial of labor to all women with one previous cesarean section and breech presentation in the current pregnancy unless there was a medical or obstetric complication that contraindicated labor. Inclusion criteria for a trial of labor included: singleton pregnancy, frank and nonfrank breech presentation, and estimated fetal weight between 1500 and 3800 gm.

Exclusion criteria included previous classical cesarean section, more than one previous cesarean section, inadequate pelvic dimensions on x-ray pelvimetry and clinical examination, and hyperextension of the fetal head grade III or IV, diagnosed by abdominal x-ray films.[6] We use x-ray pelvimetry routinely in the secundigravid patient (first labor after cesarean), but only selectively in parous patients. Fetal weight estimation was performed by clinical and ultrasonographic methods.[7]

All material and neonatal charts were retrospectively reviewed. To focus on the impact of mode of delivery, antepartum deaths, infants weighing <1500 gm, and infants with congenital anomalies incompatible with life were excluded. Of the 78 patients with breech presentation and a prior cesarean section, seven patients were excluded for this reason. The total number of patients studied were categorized into three study groups (1, 2, 3), based on the patient's mode of delivery by protocol selection and on the actual route of delivery. Statistical analysis was by χ^2 analysis. A p value of <0.05 was considered significant.

More than one previous cesarean section	5
Estimated fetal weight >3800 gm	9
Hyperextension of fetal head, grades III and IV	1
Severe preeclamptic toxemia, placenta previa, and antepartum hemorrhage	3
Total	24

Results

From January 1977 to December 1987, 71 women with previous cesarean section and singleton breech presentation in labor were studied. Twenty-four (33.8%) women were allocated to the elective repeat cesarean section group (group 1) and 47 (66.2%) to the trial of labor (group 2). Of the 47 patients allocated to the trial of labor group, 37 (78.7%) were delivered vaginally and 10 (21.3%) required repeat cesarean section (group 3).

Group 1: Elective repeat cesarean section. Of the 24 women allocated to the elective cesarean section group, all were delivered according to protocol. Indications for elective cesarean section are summarized in Table I. There were 18 multigravid patients and six secundigravid women (first pregnancy after cesarean section). All women allocated to the abdominal delivery group underwent a transverse lower-segment cesarean section. Anesthesia for these patients consisted of general anesthesia in 21 cases (87.5%) (for technical reasons of anesthesiologists) and a lumbar epidural anesthesia in 3 cases (12.5%).

Immediate neonatal outcome for each group was determined by the 1- and 5-minute Apgar scores, birth trauma, neonatal mortality, and morbidity. There were no neonatal deaths in this group. All 24 women received some systemic antibiotics during the postoperative course. However, 10 patients had febrile morbidity. Five cases of morbidity were attributed to endometritis, and three were caused by a urinary tract infection. One patient had deep vein thrombosis of the leg and one had a midline wound infection. Factors relating to maternal outcome are listed in Table II.

Group 2: Trial of labor, vaginally delivered. Of the 71 study-patients, 47 (66.2%) were selected to undergo a trial of labor. Thirty-seven (78.7%) of those patients, were delivered vaginally. There were 23 secundigravid (62.2%) and 14 (37.8%) multigravid patients. Intravenous or intramuscular analgesic (narcotic) was administered to all women. Pudendal block anesthesia was used in six of the vaginal breech deliveries.

Table II. Maternal outcome by group

	Study group		
	1 (n = 24)	*2 (n = 37)*	*3 (n = 10)*
Hospital days (mean)	8.2	3.6	9.6
Febrile morbidity (urinary tract infection, endometritis, wound infection, deep venous thrombosis)	10	2	2
Anemia requiring blood transfusion	3	1	1
Dehiscence	2	0	1
Cesarean hysterectomy	0	1	0
Vaginal hematoma	0	1	0
Total maternal morbidity*	15	5	4

*$p < 0.001$, $\chi^2 = 21.08$, $df = 2$.

Five of the patients required breast stimulation with an Egnell breast pump. None of the patients in this study required oxytocin stimulation. Before 1987 we did not use oxytocin stimulation after cesarean section. Now we administer oxytocin to patients who are undergoing a trial of labor when indicated for obstetric reasons.

One patient had induction of labor because of premature rupture of the membranes. Two women received augmentation of labor for a prolonged latent phase of labor, and two received augmentation of labor for protracted cervical dilatation in the active phase of labor. Fetal heart rate monitoring and uterine contraction monitoring were used on a continuous basis in all labors. No patterns of the fetal heart rate were judged severe enough to warrant cesarean section for fetal distress.

Delivery was by assisted breech delivery with Piper forceps for the aftercoming head (35 patients) and assisted breech delivery with manual maneuvers (2 patients). Two of the 37 vaginal deliveries were complicated by the occurrence of a nuchal arm. In one case the infant sustained mild brachial plexus injury. The infant's right upper-extremity functions improved by the time he was discharged on the fourth postpartum day. At 1 month of age, only mild right shoulder muscle weakness was present. This weakness was not apparent on reexamination at 6 and 12 months of age. Neonatal outcome for all infants is listed in Table III.

Immediate postpartum intrauterine examination was routinely done to determine uterine dehiscence in this group. There was a uterine rupture in one grandmultipara.

Case report. A 37-year-old woman, para 10, presented in labor at 38 weeks by last menstrual period with frank breech at −1 station and cervical dilatation of 3 cm.

The previous cesarean section for fetal distress was performed in her second pregnancy. She had eight normal deliveries after the cesarean section. Spontaneous labor progressed normally with a normal fetal heart rate tracing. The patient had an uneventful trial of labor and was delivered with assisted breech and forceps for the aftercoming head of a 2980 gm infant with Apgar scores of 7 and 9 at 1 and 5 minutes, respectively. Because of the previous cesarean section, postpartum intrauterine examination was done. A low transverse uterine rupture was found. Because of persistent postpartum bleeding, an exploratory laparotomy was performed. The woman also desired sterilization. During the laparotomy a low transverse uterine rupture extending to the round ligament was found. A hysterectomy was necessary for hemorrhage. The patient had an uncomplicated postoperative course.

Maternal outcome of this group is given in Table II.

Group 3: Cesarean section after trial of labor. Ten patients (10 of 47, 21.3%), six secundigravid and four multigravid women, required cesarean section after being selected for trial of labor. There were two patients delivered by cesarean section because of fetal distress.

Failed augmentation and induction of labor accounted for the majority of trial of labor "failures" in this group. Three patients (1 multigravid and 2 secundigravid) received breast stimulation for a prolonged latent and active phase of labor. Three secundigravid and one multigravid patient received nipple stimulation for induction of labor (premature rupture of membranes (three cases) and postdated pregnancy (one case). All of these women failed to progress satisfactorily in labor and were delivered by cesarean section.

Cord prolapse occurred in the first stage of labor in one patient with footling presentation. The diagnosis was made clinically and the woman underwent a cesarean section. Her infant did well.

Maternal and neonatal outcome of group 3 is given in Tables II and III. Overall, 66.2% of study patients undergoing trial of labor (47 of 71) had a successful trial of labor (78.7%, 37 of 47) and vaginal delivery (52.1%, 37 of 71).

There were 10 patients among the study groups with nonfrank breech presentation. All except two were delivered successfully by vaginal delivery. Among the neonatal outcome (p measures) statistical significance was not reached in any category.

The duration of hospitalization was longer in the cesarean section group, but these data were influenced by the hospitalization of the mothers after abdominal delivery.

Mothers and infants are usually discharged 3 to 4 days after vaginal delivery and 7 to 8 days after cesarean section. Maternal morbidity was significantly less in patients who had a vaginal delivery compared with patients undergoing cesarean delivery ($p < 0.001$). Four mothers in the cesarean section group received blood transfusions. One woman in the vaginal delivery group required a blood transfusion.

Table III. Neonatal outcome by study group

	Study group

‡$0.5 > p > 0.1$; $\chi^2 = 1.65$, $df = 2$.

Comment

Review of the literature from the British Commonwealth and United States shows that one third to two thirds of patients with a previous cesarean section will progress to a successful and safe vaginal delivery if properly selected and allowed a trial of labor.[8-11] Sixty-one (85.9%) of the 71 cases in our study were delivered according to protocol; 78.7% (37 of 47 patients) had a successful trial of labor.

During the study period 1504 women had a history of one or more cesarean sections and singleton vertex presentations in current pregnancies. The total number of patients with one prior cesarean section was 1260; 244 patients had two or more prior cesarean deliveries. Of the 1504 patients, 372 (24.8%) were selected to undergo a repeat cesarean section, and 1132 (75.2%) were allowed a trial of labor. Overall, 893 patients (78.88%) from the trial-of-labor group had a successful trial of labor and 239 patients (21.12%) failed the trial of labor and underwent cesarean section. The total vaginal delivery rate was 59.37% (893 of 1504).

The breech presentation and presence of uterine scar do not appear to significantly influence the likelihood of a successful trial of labor.

There were 10 patients in this study group with nonfrank breech presentations. The case of cord prolapse occurred in the first stage of labor and the fetus was delivered by cesarean section and did well. Many investigators report that nonfrank breech presentation is associated with a significantly higher incidence of cord

prolapse.[12, 13] The incidence of cord prolapse may be as high as 10%. However, cord prolapse does not occur in 90% of these cases; when it does occur, it is usually associated with a good fetal outcome. Cord prolapse in the nonfrank breech presentation, although an indication for cesarean delivery, usually does not have as severe an outcome as in vertex or frank breech presentations. Because the cord is prolapsed between the fetal legs, it often is not markedly compressed during subsequent contractions.[5] Two studies have failed to demonstrate any difference in outcome in frank and nonfrank breech deliveries.[4, 14]

Results of our study suggest that the neonatal outcome was not significantly influenced by the mode of delivery. As indicated in other reports, neonatal injury after delivery from breech presentation (comparison between cesarean section and carefully performed assisted breech vaginal delivery) is similar.[15] There were no maternal or perinatal deaths in any of the 47 trials of labor. The incidence of maternal morbidity after cesarean section compared with that after vaginal delivery was high.

The overall febrile morbidity in the group undergoing a trial of labor, including failures, was lower than in the group having cesarean section delivery. The apparent dehiscence incidence was higher at cesarean section than after vaginal delivery. This is probably related to the accuracy of diagnosis after a vaginal delivery compared with the direct visualization at laparotomy.[16]

The major complication of uterine rupture in the case presentation may have been related to grand multiparity, but the association with previous cesarean section, grand multiparity, and breech presentation cannot be ignored.

Despite modern operative techniques and systemic antibiotic regimens, women undergoing cesarean section experience intraoperative complications, blood loss, and infections at a higher rate than those associated with vaginal delivery. Maternal risks of morbidity multiply when the potential anesthetic and operative complications encountered in subsequent abdominal deliveries are considered. The favorable outcome of the neonate who is delivered vaginally, and the established maternal risks associated with cesarean section support the concept that in selected breech presentations pregnancies after a previous cesarean section, a vaginal delivery can be performed without increased risk to either mother or infant.

There is no apparent advantage of cesarean section for the neonate. The experience of Green et al.[17] in the Montreal study clearly demonstrates that the increase in cesarean section rate did not affect breech outcome. Cesarean sections are performed to protect the mother or the fetus. Elective repeat cesarean section frequently does not achieve either goal.[18]

In summary, a selective protocol for management of breech presentation after previous cesarean section seems acceptably safe. A trial of labor decreases the total number of cesarean births. It appears that if there is risk associated with allowing a trial of labor, it is small or less than that associated with repeat cesarean section. Consideration of these principles may aid both the clinician and the patient when deciding to allow a trial of labor in the management of breech presentation after previous cesarean section.

Vaginal birth after cesarean delivery in the twin gestation

Thomas H. Strong, Jr., MD, Jeffrey P. Phelan, MD, Myoung Ock Ahn, MD, MPH, and Albert P. Sarno, Jr., MD, Maj., USA

Los Angeles, California

The pregnancy outcomes of 56 women with a twin gestation and a prior cesarean birth were analyzed to determine whether a trial of labor was a reasonable consideration. Of these patients, 31 (55%) underwent an elective repeat cesarean delivery and 25 (45%) attempted vaginal delivery. Of those who attempted vaginal delivery, 18 (72%) were vaginally delivered of both infants. The dehiscence rate among women with twin pregnancies who attempted a trial of labor was 4% compared with 2% in women with singleton pregnancies. There were no significant differences in maternal or neonatal morbidity or mortality rates in trial of labor versus no trial of labor groups. We conclude in this limited population that a trial of labor in a twin gestation after a previous cesarean delivery appears to be a reasonable consideration. The usual safeguards for attempted vaginal delivery in the twin gestation should be followed. (AM J OBSTET GYNECOL 1989;161:29-32.)

Key words: Trial of labor, vaginal birth after cesarean section

Vaginal birth after cesarean delivery is considered an acceptable alternative to routine elective repeat cesarean delivery.[1] In some cases, vaginal birth after cesarean delivery may represent the safest delivery method for the pregnant woman and her fetus. Initially a choice available to those patients who satisfied limited entry criteria such as a singleton pregnancy with a vertex presentation and one prior low-transverse uterine scar, studies suggest that favorable maternal and neonatal outcomes can be expected for many women who do not satisfy these criteria.[1, 2]

Inherent in cesarean birth are increased maternal morbidity and mortality rates and greater expense for the patient with a cesarean delivery.[3] Some authors have attempted to broaden the acceptance criteria for vaginal birth after cesarean delivery (multiple prior cesarean deliveries, unknown uterine scar, and breech presentation), but no study has focused on vaginal birth after cesarean delivery as an alternative for women with a prior cesarean delivery and a twin gestation.[1] Twins, which occur in approximately 1% of all pregnancies,[4] represent a small but significant group of patients who might be considered candidates for a trial of labor after a prior cesarean delivery. But vaginal birth after cesarean delivery in twin gestations has been rarely described.[5-8] A review of the literature disclosed only 23 cases of a trial of labor after a prior cesarean delivery and all achieved a vaginal delivery.[5-8] Therefore, the purpose of this study is to present detailed information on the pregnancy outcomes of 56 women with a prior cesarean delivery and a twin gestation.

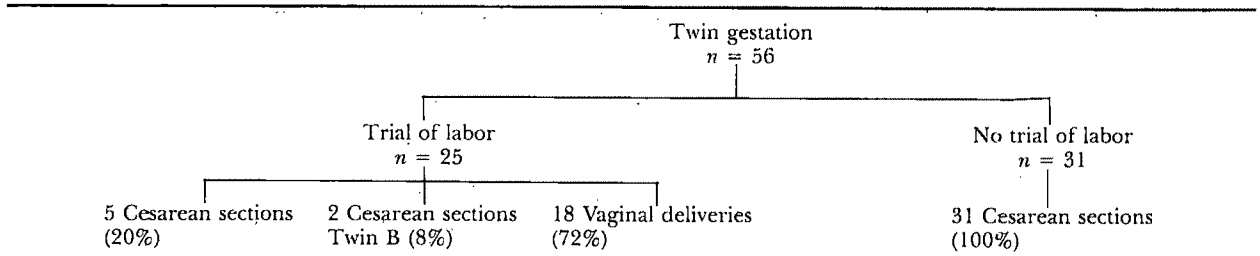
Material and methods



The records of all gravid women with at least one prior cesarean birth who were seen at the Labor and Delivery Suite of the University of Southern California School of Medicine from July 1, 1982, to June 30, 1986, were reviewed. A trial of labor was considered in those women with a twin gestation and a prior cesarean delivery. Trial of labor was not considered if immediate operative intervention was needed or if a malpresentation was diagnosed in twin A. All other women were offered a trial of labor. A variety of maternal and fetal outcome variables were collected and data were analyzed by the Fischer exact test. Comparisons were made between the trial of labor and nontrial of labor groups.

Results

A total of 6250 gravid women with a prior cesarean delivery were delivered of infants during the study period. Of these, 62 (1%) had a twin gestation. Fifty-six of these patients had sufficient information available for review and analysis.

Among the 31 patients (55%) who did not undergo a trial of labor, a repeat cesarean delivery was undertaken. The indications for the repeat cesarean delivery in the group without a trial of labor were: elective, 14 (45%); malpresentation (twin A), 11 (35%); pregnancy-induced hypertension, 3 (10%); and other, 3 (10%). Of the 25 (45%) who attempted a vaginal delivery, 18 (72%) were delivered of both infants vaginally (Table I). A repeat cesarean delivery was undertaken in seven patients (28%) because of the following indications:

Table I. Outcome of delivery

malpresentation of twin A diagnosed in the active phase of labor, 4 (57%); fetal distress in twin B, 2 (29%); and failure to progress, 1 (14%). Of those who attempted a vaginal delivery, the number of prior cesarean deliveries was one (21, 84%) and two (4, 16%). There were 18 patients (64%) who had an unknown scar. Seven patients (28%) received oxytocin for induction or augmentation of labor, with a dose range of 3.0 to 22.8 mU/minute and a mean of 5.7 mU/minute. Of these, six (86%) were vaginally delivered.

The indications for the primary cesarean deliveries of the 25 women with twin gestations who attempted vaginal delivery are illustrated in Table II. Unlike singleton pregnancies, successful vaginal delivery rates appeared to be unrelated to the reason for the primary cesarean delivery.

The mean birth weight and estimated gestational age among the group with repeat cesarean delivery were 36.2 weeks and 2488 gm, respectively. Likewise, among the group with trial of labor mean birth weight and estimated gestational age were 33.1 weeks and 2283 gm, respectively. The mean birth weight of the trial of labor "A" twins was 2309 gm versus 2281 gm for the trial of labor "B" twins. Among the B twins in the group with trial of labor, eight were nonvertex presentations. Two of eight (25%) were delivered by complete breech extraction.

After delivery, the uterus was examined for evidence of rupture or dehiscence. One patient was noted to have a single 4 cm transverse dehiscence in the lower uterine segment after a vaginal delivery of a vertex-breech set of twins. The rupture or dehiscence rate of the 25 women with twin gestations who attempted a trial of labor was 4% (1 of 25) as compared with a rate of 2% for the singleton vaginal birth after cesarean delivery patients who were delivered of infants during the same study period.

There were six neonatal deaths among the women who underwent trial of labor. All were attributable to extreme prematurity. The mean gestational age of this group was 22.3 weeks (range, 21 to 24 weeks). Among the neonatal deaths, no anomalies were noted. One hysterectomy was performed secondary to placenta accreta and occurred during a repeat cesarean delivery (Table III). There were no significant differences in maternal or neonatal morbidity and mortality rates in any comparison of trial of labor versus no trial of labor.

Comment

Previous investigators have routinely excluded women with a prior cesarean delivery and a twin gestation from a trial of labor. A concern expressed by Kaltreider and Krone[9] was that uterine overdistention, which can occur in twin gestations, would increase the risk of uterine rupture. However, a review of 23 sets of twins delivered vaginally during the early 1960s failed to demonstrate such an occurrence.[5-8] Moreover, neither Pedowitz and Schwartz[10] nor Phelan and associates[11] were able to substantiate a relationship between uterine overdistension and uterine rupture.

In a 30-year review of the English language literature, two thirds of singleton candidates for vaginal birth after cesarean delivery who were allowed a trial of labor were delivered of infants vaginally, with a 0.7% rupture rate.[3] In the current study, 72% of women with a twin gestation and prior cesarean delivery who were given a trial of labor were vaginally delivered of both infants, with a dehiscence rate of 4% and no uterine rupture. This compares favorably with the success and dehiscence rates at our institution of singleton pregnancies with a prior cesarean delivery over the same study period (80% and 2%, respectively). It is noteworthy that the vaginal delivery rate of the prior cesarean delivery patients with a twin gestation who were delivered of at least one twin vaginally also was 80%. The reason for the single dehiscence in our study group could be related to the combination of multiple prior cesarean deliveries, oxytocin augmentation, midforceps rotation of twin A, and Piper forceps placement of twin B. However, this seems unlikely in light of the recent evidence of Ahn and associates[12] and the data of Horenstein et al.[13]

Paul and associates[14] suggest that "the indication for a prior cesarean delivery bears little influence as it re-

lates to the success of achieving a vaginal delivery in a current pregnancy." With this principle in mind, all women without an obstetric or medical contraindication to labor during the study period were offered a trial of labor. Unlike patients with one prior cesarean delivery, the vaginal delivery rate, however, was not similarly affected by the prior indication for cesarean delivery (Table II) or the use of oxytocin. The relatively high success rate of twins being delivered vaginally after a previous cesarean delivery because of arrested labor is probably a result of the smaller size of the twin fetus as compared with the term singleton.

Other authors suggest that a trial of labor in women with multiple prior cesarean deliveries[1, 15] or an unknown scar type[1, 2] is reasonable and not associated with an increased risk of morbidity or mortality. In accordance with these findings, patients with twin gestations were also permitted a trial of labor. This practice was not associated with an increased risk of maternal or fetal morbidity or mortality.

Neonatal mortality among the entire group with twin gestation and prior cesarean delivery was 8%. This compares favorably with the reported frequency of twin neonatal mortality rates.[16] In that report, it was noted that as the gestational age increased, neonatal mortality decreased. This is in keeping with our findings in which all neonatal deaths were secondary to extreme prematurity.

As experience increases with patients with vaginal birth after cesarean delivery, a greater number of the patients with a twin gestation will desire a trial of labor. If a trial of labor is considered in these patients, continuous electronic fetal monitoring of both twins would appear prudent. Candidates for attempted vaginal delivery should be limited to those pregnancies in which twin A is in a vertex presentation. After the delivery of twin A, real-time ultrasonography should be used to evaluate the lie, presentation, and heart rate of twin B. A concern among practitioners who manage patients with prior cesarean deliveries involves the risks of intra- or extrauterine manipulations. Whereas the number of such manipulations performed in our population was too small to clarify this issue, information from this report and others[16, 17] suggest that version is not an unreasonable consideration. Therefore, if twin B is a malpresentation, exernal cephalic version, internal podalic version, or outright cesarean delivery would appear to be acceptable management alternatives.[17] Cesarean delivery of twin B should be reserved for those circumstances in which fetal distress is present and vaginal delivery cannot be safely accomplished within a reasonable time.

In summary, the present series corroborates the work of others[5-8] in that vaginal birth after delivery in the twin gestation is not associated with an increased risk of perinatal or maternal morbidity and mortality. Though a trial of labor in the twin gravid woman with a prior cesarean delivery remains controversial, our contemporary experience suggests that it is a reasonable consideration in the properly selected patient. If attempted vaginal delivery is undertaken, the usual safeguards for a trial of labor in a twin gestation should be followed.

Pharmacokinetics of orally administered ritodrine

Steven N. Caritis, MD, Raman Venkataramanan, PhD, Margaret Cotroneo, RN, and Jye-Ping Chiao, MS
Pittsburgh, Pennsylvania

The oral dosing regimen for ritodrine was based in large part on kinetic data obtained in nonpregnant subjects. There are limited kinetic data after oral administration of ritodrine in pregnancy. The purpose of the present study was to compare ritodrine kinetics in pregnant and nonpregnant women, evaluate the effect of feeding on ritodrine absorption in pregnant women, and determine if the plasma concentration of ritodrine is proportional to the dose administered in nonpregnant women. Plasma concentrations after a single 20 mg dose of ritodrine were significantly greater in fasting nonpregnant women than in fasting pregnant women. The area under the concentration time curve was 1372 ± 385 and 1001 ± 257 ng/ml/min, respectively. In pregnant women ingesting 20 mg of ritodrine, plasma concentrations were not significantly different in the fed or fasted state; plasma concentrations peaked at 11 ng/ml and were less than 3 ng/ml within 4 hours. In nonpregnant subjects the concentration of ritodrine in plasma was proportional to the dose. After ingestion of 10, 20, or 30 mg of ritodrine, the area under the curve was 751 ± 253, 1372 ± 385, and 2148 ± 571 ng/ml/min, respectively. These data indicate that ritodrine concentrations in pregnant women after a 20 mg oral dose are low. Increases in dosage will probably result in proportional increases in plasma concentration. The maximal dose of ritodrine recommended for prevention of recurrent preterm labor should be increased. (AM J OBSTET GYNECOL 1989;161:32-5.)

Key words: Ritodrine, kinetics, oral dosage, pregnancy

Ritodrine was approved for the treatment of preterm labor in 1980. Regimens for both intravenous and oral administration were in large part developed from kinetic studies in nonpregnant women and male volunteers. Pregnancy is characterized by changes in plasma volume, plasma protein concentration, renal blood flow, intestinal transit time, and a multitude of other factors that can affect ritodrine absorption, distribution, or elimination.[1, 2] The highest dose of oral ritodrine recommended for continuing therapy of preterm labor is 120 mg/day, but this recommendation is not based on kinetic studies in pregnant women. Smit et al.[3] and Van Lierde et al.[4] have suggested that the plasma concentrations achieved with this dosage of rito-

drine are unlikely to sustain labor inhibition. Indeed, we have shown that 120 mg/day of ritodrine is significantly less effective than 30 mg/day of terbutaline in preventing recurrence of preterm labor.[5] It is unclear if adequate ritodrine concentrations could be obtained with the present formulation merely by increasing the oral dosage above 120 mg/day. Also, it is unclear if ritodrine absorption could be enhanced in pregnancy by administering the drug before meals. The purpose of the present study was threefold: (1) to define the kinetics of orally administered ritodrine in pregnant and nonpregnant subjects, (2) to evaluate the effect of feeding on ritodrine absorption in pregnant women, and (3) to determine if plasma concentration increased proportionally with an increase in the dose of ritodrine.

Material and methods

After approval by the Research Review and Human Experimentation Committee of Magee-Womens Hospital, we obtained informed consent from 10 nonpregnant and 10 pregnant nonlaboring women for participation in this study. Excluded from the study were women with a contraindication to β-agonist medication and women receiving theophylline or other tocolytic therapy.

Pregnant women at gestational ages of 20 to 34 weeks received 20 mg of ritodrine orally on different days, once after an overnight fast, and once 60 minutes after eating a standardized breakfast. Breakfast consisted of one soft boiled egg, one slice of toast, one 4-ounce cup of juice, and one 8-ounce glass of nonfat milk. Fasting nonpregnant women received either 10, 20, or 30 mg of ritodrine orally in random order on different days. In all women at least 48 hours elapsed between each study. On the day of study, women did not ingest caffeine. Blood (7 ml) was removed from an indwelling cannula (heparin lock) before and at 11 times in the 6 hours after drug ingestion (10, 20, 30, 45, 60, 90, 120, 180, 240, 300, and 360 minutes). Blood was collected in heparinized syringes and immediately centrifuged at 2000 rpm. The supernatant plasma was frozen at −20° C until analyzed for ritodrine concentration by high-performance liquid chromatography with electrochemical detection.[6] The area under the plasma concentration versus time curve from time 0 to the last measured point was calculated by the trapezoidal method.[7] Terminal disposition rate constant and disposition half life were calculated according to standard techniques.[7]

Differences in pharmacokinetic parameters were compared by paired or nonpaired *t* test or by repeated measures analysis of variance where appropriate.[8] Data are expressed as mean ± SD.

Results

The pharmacokinetics of ritodrine in 10 pregnant and 10 nonpregnant subjects are compared in Table I. All subjects received 20 mg of ritodrine while fasting. The area under the curve was significantly greater in nonpregnant women. Peak plasma concentrations were also greater in nonpregnant subjects but not significantly so. Four hours after ritodrine ingestion, ritodrine concentration was 3 ng/ml or less in all subjects. The time to peak concentration was significantly shorter in nonpregnant subjects.

The effect of feeding on ritodrine pharmacokinetics in pregnant women is summarized in Table II. All 10 subjects received 20 mg of ritodrine once in the fed and once in the fasted states. The area under the concentration time curve, and the peak plasma concentrations were greater and the absorption was more rapid during fasting than after eating. However, none of these variables was significantly different in the fed or fasted state. Four hours after ingestion of ritodrine, plasma concentrations were 3 ng/ml or less in all subjects. The elimination half-life was not altered by fasting.

Table III describes the relationship between ritodrine dosage and plasma concentration in 10 nonpregnant subjects. The area under the curve and peak plasma concentration increased proportionally to the dose. The ritodrine concentration was also proportional to the dose administered 4 hours after ingestion.

Table III. Relationship between ritodrine dosage and plasma concentration in nonpregnant subjects

	10 mg	*20 mg*	*30 mg*
AUC (ng/ml/min)	751 ± 253	1372 ± 385	2148 ± 571
Concentration (ng/ml)			
At peak	6.6 ± 2.9	13.4 ± 5.2	20.1 ± 8.2
At 4 hr	1.3 ± 0.9	2.3 ± 0.8	3.4 ± 1.4
Time to peak (min)	29 ± 13	30 ± 14	50 ± 38

AUC, Area under the curve.

The time to achieve peak concentrations did not differ significantly in the three groups.

Comment

We have demonstrated significant differences between pregnant and nonpregnant subjects in the kinetics of orally administered ritodrine. After oral ingestion, ritodrine plasma concentrations were lower in pregnant women as was the area under the concentration time curve. Pregnant women absorbed ritodrine significantly slower than nonpregnant women. Lower plasma concentrations in pregnant women may be the result of poorer absorption, greater elimination, or distribution into a greater volume than in nonpregnant subjects. From the present study we cannot determine which of these factor(s) is responsible for the differences in pregnant and nonpregnant subjects.

Ritodrine absorption was not enhanced to any significant degree by the presence of food. In fasting pregnant women, peak plasma concentration after a 20 mg dose averaged only 11 ng/ml (range, 4 to 21 ng/ml). The concentration decreased rapidly and averaged approximately 2 ng/ml 4 hours after ingestion of the drug. With repeated doses of ritodrine, the peak concentration will increase somewhat as will the concentration at 4 hours. In the study of Smit et al.,[3] plasma concentrations in pregnant women receiving ritodrine for at least 3 days averaged 19 ng/ml at peak (range, 10 to 31 ng/ml) and 7 ng/ml 4 hours after ingestion (range, 5 to 10 ng/ml).

We performed dose proportionality studies in nonpregnant rather than pregnant subjects for ethical reasons. We did not wish to subject pregnant women to three different studies in which blood was withdrawn, and we were concerned that the 30 mg dose might cause side effects. We demonstrated proportionality between ritodrine dosage and plasma concentration in nonpregnant subjects. Linear pharmacokinetics of ritodrine have been demonstrated in pregnant and nonpregnant subjects receiving intravenous ritodrine over a very wide dose range.[4, 9] We have assumed that proportionality between oral dosage and plasma concentration exists in pregnant women because factors such as plasma volume and clearance that alter ritodrine kinetics in pregnancy are unlikely to effect the relationship between dose and plasma concentration. A relationship between oral dosage and plasma concentration has been demonstrated for doses of 5 and 10 mg of ritodrine,[4] and there is no evidence that this relationship should not exist with doses up to 30 mg.

The lowest concentration of ritodrine achieved during intravenous therapy ranges from 15 to 31 ng/ml.[9] Concentrations of 80 ng/ml or more are commonly required to initially inhibit preterm labor.[9] The concentration of ritodrine required to sustain labor inhibition has not been established. However, it is clear that 120 mg/day, that is, 20 mg orally every 4 hours, is insufficient to prevent recurrent preterm labor in a substantial percentage of patients.[5] This clinical observation, coupled with the large variability in plasma concentrations between subjects in this study and in the study of Smit et al.,[3] suggest that higher ritodrine dosages can be used to prevent recurrent preterm labor. Not every patient may require a higher dosage, but those with poor absorption or rapid clearance of ritodrine will. The intravenous tocolytic dosage of ritodrine is established by incremental increases in the infusion rate until contractions are inhibited or side effects occur. A similar approach appears to be reasonable for orally administered drug. A starting dose of 120 mg is unlikely to lead to side effects and will be effective in some women. If a response is not achieved, the dose can be increased accordingly.

Higher oral doses of ritodrine will not address the problem of inconvenience caused by a dosing frequency of every 4 hours. Similar problems exist with terbutaline, which is also administered orally every 4 hours.[9] A more desirable formulation of ritodrine has recently been developed.[10] This sustained release capsule can be administered every 8 hours and provides concentrations of 18 and 11 ng/ml 4 and 8 hours after ingestion of an 80 mg dose. This formulation is not yet available in this country.

In summary, we have demonstrated that the plasma concentration of ritodrine after an oral dose of 20 mg is lower in pregnant than in nonpregnant women. The concentration of ritodrine in pregnant women ingesting a 20 mg dose is low. The maximal dosage of 120 mg/day is unlikely to adequately sustain labor inhibition in many women.

Neuromuscular blockade with magnesium sulfate and nifedipine

Scott W. Snyder, MD, and Michael S. Cardwell, MD
Columbia, Missouri

A patient who received tocolysis with nifedipine developed neuromuscular blockade after 500 mg of magnesium sulfate was administered. This reaction demonstrates that nifedipine can seriously potentiate the toxicity of magnesium. Caution should be exercised when these two tocolytics are combined. (Am J Obstet Gynecol 1989;161:35-6.)

Key words: Nifedipine, magnesium, drug interaction, neuromuscular blockade

Nifedipine has been used as a tocolytic in the treatment of premature labor and has been compared favorably to ritodrine.[1] Because both magnesium sulfate and nifedipine are calcium channel blockers, some interaction might be expected as both are undoubtedly involved in the alteration of the movement of calcium across membranes in the myometrium.

Recently a report appeared that described hypotension in preeclamptic patients who received both agents: nifedipine for the treatment of pregnancy-induced hypertension and magnesium sulfate as an anticonvulsant. We report a patient who developed skeletal muscle neuromuscular blockade with a small dose of magnesium sulfate after tocolysis with nifedipine.

Case report

This 22-year-old patient, gravida 4, para 2, was seen with contractions and effacement of the cervix at 32 weeks' gestation. The patient had one previous first-trimester loss and two previous premature births of an 1872 gm infant and a 2152 gm infant who survive. The patient had had some contractions in the 2 weeks before admission but no descent of the presenting part or effacement of the cervix.

On the night of admission, contractions had become regular and of 45 seconds' duration. The cervix was 50% effaced, a change from examination 4 days earlier. The patient was hydrated with 1000 ml lactated Ringer's solution without change in labor. Nifedipine was started and the patient received 60 mg orally over the next 3 hours. This resulted in a marked decrease in duration and frequency of contractions. A maintenance regimen of 20 mg every 8 hours was begun. Contractions recurred 12 hours later. Because we thought a maximum maintenance dose of nifedipine was being administered, magnesium sulfate was chosen. After 500 mg of intravenous administration of magnesium, the patient developed jerky movements of the extremities, complained of having difficulty swallowing, had paradoxical respirations, and was unable to lift her head from the pillow. The magnesium was discontinued and the muscle weakness resolved over the next 25 minutes.

Contractions ceased and were not a problem

throughout the remainder of the 3-day hospitalization. The patient was discharged while taking nifedipine, 20 mg every 6 hours. The pregnancy continued and the patient was delivered of a 3490 gm boy at 38 week's gestation.

Comment

The mechanism of action of both nifedipine and magnesium in the suppression of uterine contractility is obscure. Both agents block intracellular flow of ionized calcium in both skeletal and smooth muscle. Smooth muscle relaxation may be more profound than that of skeletal muscle because of limited reserves of calcium in endoplasmic reticulum of smooth muscle. In skeletal muscle, magnesium has clear prejunctional and postjunctional effects, and at high levels can produce neuromuscular blockade. Magnesium has been shown to potentiate both depolarizing and nondepolarizing neuromuscular blockers. Although some conflicting reports of potentiation of neuromuscular blockers by nifedipine on animal in vitro and in vivo muscle preparations have appeared,[2] we are not aware of any reports of serious interactions in humans, despite the relative frequency with which the combination of these agents is seen in practice.

We think that our patient's reaction suggests that nifedipine potentiates the neuromuscular blockade effect of magnesium sulfate. We recommend that nifedipine and magnesium not be used for tocolysis in the same patient. Choosing an agent with another mechanism of action, for example, β-sympathomimetics, may be a safer and more logical choice when an additional tocolytic seems indicated.

Usefulness of continuous fetal heart rate monitoring during cesarean section

Boris M. Petrikovsky, MD, PhD, Mario Cohen, MD, and M. Leon Tancer, MD

Brooklyn, New York, and Farmington, Connecticut

Cesarean section performed because of fetal distress routinely leaves the fetus unmonitored for a variable period of time (perioperatively and intraoperatively). We present in this report two cases in which continuous fetal heart rate monitoring during cesarean section modified the obstetric management for the benefit of the mother and of the fetus. (Am J Obstet Gynecol 1989;161:36-7.)

Key words: Cesarean section, fetal heart rate, fetal distress

Fetal distress is one of the major indications for the performance of primary cesarean sections. Overall, there has been a greater than threefold increase in the number of cesarean sections during the last decade in the United States; fetal distress represents the reason for 13.2% of all cesarean sections.

It has been a routine practice to discontinue fetal heart rate monitoring before the performance of a cesarean section. Thus the fetus, already compromised, remains unmonitored throughout the entire surgical procedure, and the obstetric team (obstetrician, anesthesiologist, and neonatologist) is unaware of the current fetal status.

Beginning in June 1985, we extended intrapartum fetal heart rate monitoring to the intraoperative period in cases in which indications for cesarean section arose during labor. This report deals with the practical usefulness of intraoperative fetal heart rate monitoring.

Case reports

Case 1. A 32-year-old patient, gravida 2, para 1, was admitted to the hospital for a trial of vaginal delivery after a previous cesarean section. The patient was moderately obese.

Labor progressed uneventfully until 6 cm of cervical dilation was reached. At this point, the internal fetal

heart rate monitor registered moderate variable decelerations. A pelvic examination was performed and umbilical cord prolapse was ruled out. Conservative measures (such as changes in maternal position and oxygen) were not successful. Twenty minutes later, variable decelerations became severe; scalp pH was 7.20. At this point, a decision was made to perform a cesarean section. The internal scalp electrode was left in situ and fetal heart rate monitoring was continued. The fetal heart rate returned to normal after the tracheal intubation was completed and remained normal throughout the entire procedure.

When the peritoneal cavity was entered, the surgeons found multiple adhesions between the loops of the small bowel, omentum, and the uterus, which necessitated meticulous and time-consuming dissection. The identification of the vesicouterine fold and dissection of the bladder flap was also technically difficult.

The neonate was born in satisfactory condition. There were two loops of umbilical cord around the fetal neck. The Apgar score was 8 at 1 minute and 9 at 5 minutes. Cord venous pH was 7.28. Fetal weight was 4200 gm. Estimated blood loss was 700 ml.

Case 2. A 26-year-old patient, gravida 1, para 0, was admitted to the hospital in active labor with spontaneously ruptured membranes. Pelvic examination revealed the cervix to be 3 cm dilated and fully effaced. An internal electrode was placed and registered late decelerations and diminished beat-to-beat variability. The scalp pH was 7.18. A decision was made to perform an emergency cesarean section.

The fetal heart rate tracing improved after the tracheal intubation and remained stable up to the time of the uterine incision, which permitted the surgeon to proceed up to this point without haste. Immediately after the myometrial incision, the fetal heart rate dropped abruptly without a tendency to recover. Expeditious delivery of the fetus was undertaken by the senior operator.

The neonate was born with mild hypoxia. The 1-minute Apgar score was 5; the 5-minute score was 8. The venous cord pH was 7.21, and the estimated blood loss was 950 ml.

Comment

Schaefer et al.[1] stated that indications for undertaking cesarean section may serve as a clue to the physician as to possible complications. Thus the complication rate for emergency operations is almost five times higher than that for elective cesarean sections. These authors registered a 9.5% increase in the occurrence of the following complications during cesarean sections performed in a "rushed" fashion: lacerations of the isthmic part of the uterus, extension of the initial uterine incision with bleeding, and excessive blood loss necessitating blood transfusion.[1]

Major surgical complications under these circumstances were noted in 2.5% of the cases and included bladder injury, intestinal injury, laceration of one or both uterine arteries, and extension of the uterine incision into the broad ligament with subsequent development of hematoma.

Increased surgical speed and vigorous attempts to deliver the fetus may also result in neonatal trauma. Direct fetal injuries either by knife or scissors that necessitate repair by plastic surgeons, femoral fractures, peripheral nerve injury, and other injuries have been described in the literature. The unanimous opinion of all involved in researching cesarean complications is that their advoidance depends largely on the use of a controlled technique. We think that intraoperative fetal heart rate monitoring helps to achieve this goal. Thus a reassuring fetal heart rate pattern (case 1) allowed surgeons to proceed throughout the entire procedure in a patient at high risk (obesity, intraabdominal adhesions, large fetus) without haste.

If the fetal heart rate deteriorates at some point during cesarean section, the surgeon and the neonatologist are aware of it immediately because of continuous monitoring and can take appropriate measures to deliver the fetus as soon as possible and be fully prepared for the immediate resuscitation. Two steps in the course of the cesarean section require special attention, abdominal preparation and myometrial incision, because they are commonly associated with fetal heart rate changes.[2]

Risk factors for vulvar lichen sclerosus

Mario Sideri, MD,[a] Fabio Parazzini, MD,[b] Maria Teresa Rognoni, MD,[a] Carlo La Vecchia, MD,[b, c] Eva Negri, ScD,[b] Salvatore Garsia, MD,[a] Elena Arnoletti, MD,[a] and Gabriela Cecchetti, MD[b]

Milan, Italy, and Lausanne, Switzerland

To assess risk factors for vulvar lichen sclerosus data were collected in a case-control study of 75 cases and 225 age-matched control subjects. Questions concerned personal characteristics and habits, gynecologic and obstetric data, general indicators of sexual habits, and selected dietary habits. The risk of vulvar lichen sclerosus was greater in parous women than nulliparous women, but there was little tendency for the risk to increase with number of births; the finding was not significant when only married women were considered. There was no material difference between cases and control subjects in relation to major indicators of sexual habits (age at first intercourse and number of sexual partners). A smaller proportion of cases was married, but no difference was observed in the distribution of cases and controls with reference to education, smoking habits, body mass index, and previous history of diabetes. There was no association between retinoids and risk of vulvar lichen sclerosus, but intake of carotenoids was inversely and strongly associated with vulvar lichen sclerosus. This apparent protection did not materially change after adjustment for socioeconomic status and other potential confounding factors. (Am J Obstet Gynecol 1989;61:38-42.)

Key words: Risk factors, vulvar lichen sclerosus, reproductive factors, diet

Lichen sclerosus is an uncommon disease whose diagnostic features are lichenoid, slightly atrophic lesions with characteristic histologic features. An immunologically mediated pathogenesis has been claimed[1] on the basis of a reported higher frequency of autoimmune disorders[2] and specific HLA antigens in lichen sclerosus cases.[3] Immunologic factors may well explain part of the approximate tenfold greater frequency in women than in men,[4] because most autoimmune diseases are more frequent in women. Hormonal factors also may contribute to this elevated frequency in women.

The clinical observation that lichen sclerosis is more common in women with a history of repeated vaginitis[4] or in men with phimosis has suggested potential infective mechanisms.[5] However, little epidemiologic evidence is available to quantify the role of these factors. Therefore we considered the relationship between various environmental factors and vulvar lichen sclerosus, with data from a case-control study conducted in Lombardy, Northern Italy.

Subjects and methods

Between January 1985 and May 1987 trained interviewers identified and questioned women with vulvar lichen sclerosus and control subjects using a structured questionnaire. Despite the sensitive nature of the interview, the participation rate was practically complete (one case and two eligible controls refused the interview).

The cases were all women with histologically confirmed diagnosis of vulvar lichen sclerosus, according to the classification of the International Society for the Study of Vulvar Disease, who were admitted during the study period to the First Obstetrics and Gynecology Clinic of the University of Milan. A total of 75 subjects, aged 28 to 72 years (median age, 56 years), met these criteria.

The control subjects were patients admitted for acute conditions to the Ospedale Maggiore (including the four major teaching and general hospitals in Milan) and several specialized university clinics serving a catchment area comparable to that of the hospital where cases had been identified. Three controls were age-matched with each case in 5-year intervals; a total number of 225 subjects were interviewed. Of these, 29% were admitted for traumatic conditions (mostly fractures and sprains), 26% had nontraumatic orthopedic disorders (mostly low back pain and disk disorders), 20% were admitted for acute abdominal diseases that generally required surgery, and 25% had other illnesses such as disorders of the ear, nose, throat, or teeth.

Information was obtained concerning personal characteristics and habits, gynecologic and obstetric data, related medical history, and general indicators of sexual habits (age at first intercourse, total number of sexual partners). The subjects were also questioned about

their frequency of consumption per week of the major sources in the Italian diet of retinoids (milk, liver, and meat) and carotenoids (carrots and green vegetables).

Data analysis

Odds ratios (as estimators of relative risks) and 95% confidence intervals[6] were computed with use of an unmatched approach; when appropriate, relative risks were tested for trend.[7] Potential confounding factors were controlled individually with stratification and the Mantel-Haenszel procedure.[8] However, since adjustments for age or other factors did not materially change most of the relative risks, unadjusted estimates were chosen for presentation except where indicated in the text. Indexes of monthly retinol and β-carotene intake were computed using Italian Department of Agriculture standard tables of nutrient values.[9] Obviously, because the limited dietary information did not include all possible sources of dietary vitamin A, these computed indexes should be interpreted merely as approximated estimates of intake.

Results

The relationship between reproductive, gynecologic factors and vulvar lichen sclerosus is considered in Table I. The risk of vulvar lichen sclerosus was greater for parous than nulliparous women, but there was little tendency for the risk to increase with number of births (point estimates, 3.0 for women with one or two births and 3.2 for those with three or more births). This finding was significant in the overall series but not when only married women were considered. The estimated relative risks were respectively 1.8 (95% confidence

interval 0.7-4.5) and 1.7 (95% confidence interval 0.7-4.9) in women with one or two and three or more births (χ_1^2 for linear trend = 0.96, NS). No correlation emerged with number of spontaneous abortions and age at first pregnancy (data not presented). Similarly, there was no association between vulvar lichen sclerosus, menopausal status, and age at menopause (Table I).

There was no material difference between cases and controls in relation to major indicators of sexual habits (age at first intercourse and number of sexual partners, Table II).

The distribution of cases and controls according to the estimated indexes of monthly intake of retinoids (preformed vitamin A) and caroteinoids (provitamin A) is presented in Table III. There was no apparent relation between retinoid intake and the risk of vulvar lichen sclerosus but women in the upper category of carotenoid intake were at significantly lower risk.

A smaller proportion of cases was unmarried or had ever smoked (the latter finding was not statistically significant), but there were no differences between the distribution of cases and controls with regard to education or body mass index (Table IV). A previous diagnosis of diabetes was reported by a similar percentage of wowen with vulvar lichen sclerosus (8%) and the control group. No cases or controls had a history of clinically diagnosed immune connective disorders (e.g., systemic lupus erythematosus).

Comment

Two different patterns emerged from this exploratory epidemiologic investigation of vulvar lichen sclerosus. First, there were significant associations with marital status (since approximately 10% of controls but

none of the cases were never married) and with nulliparity. The possibility of selection bias being responsible for this could not be excluded, since unmarried women are probably less careful about problems of the external genital organs. It is generally difficult to quantify the role of selection bias in studying a disease when its diagnosis can be noticeably influenced by subjective factors, although in this study no major differences in socioeconomic indicators emerged between cases and controls. Furthermore, cases and controls were chosen from hospitals and institutions that covered broadly comparable catchment areas; participation in the study was almost complete.

The association with parity may be considered with regard to hormonal factors. Lichen sclerosus is more frequent in women and is generally diagnosed in the perimenopausal age (when estrogen levels are proportionally elevated and progesterone levels are decreased in relation to the inconsistent pattern of ovulation). However, in our study menopausal status and age at menopause were not related to the frequency of vulvar lichen sclerosus. These results and the observation that therapy with female hormones had no effect on the clinical course of the disease suggest that female hormones do not play an important role in the pathogenesis of vulvar lichen sclerosus. Conversely, the observation that women who had ever smoked had a lower risk of vulvar lichen sclerosus might be linked to the elevated androgen levels in smokers.[10] Although not statistically significant, this association has a plausible biologic explanation because testosterone has been advocated as the first-choice treatment for vulvar lichen sclerosus.[11]

The second major finding of this study was the negative correlation with carotenoids. This association could not be simply explained by confounding, because allowance for potential confounders (including indicators of socioeconomic and marital status) failed to account for it. Furthermore, at the time of data collection, the possible relationship between diet and vulvar lichen sclerosus was unknown to the interviewers and to the subjects interviewed, and only a small part of the questionnaire was related to dietary factors. Hence, the interviewers and the patients' attention was probably not concentrated on those aspects.

A limitation of this study is the small number of dietary variables collected. However, because the food items analyzed represent the major sources of dietary vitamin A in the Italian diet, we believe that the estimates are probably at least reasonably correlated with the real values. There is no obvious biologic explanation of this finding. The association with carotenoids but not retinoids could be related to the fact that serum levels of the former, but not the latter, are directly related to dietary intake.[12] In vitro, vitamin A inhibits human fibroblasts and collagen production.[13] Thus a deficiency of vitamin A has been claimed in the pathogenesis of skin diseases characterized by excess collagen formation. Because of this, etretinate has been proposed for the treatment of vulvar lichen sclerosus.[14-16]

The clinical observation of previous vaginitis in patients with vulvar lichen sclerosus[4] suggested that infections may play a provocative or localizing role. However, number of sexual partners and age at first intercourse (two well-established indirect indicators of the risk of sex-related diseases) were not associated with the risk of vulvar lichen sclerosus in this series.

On the basis of clinical data, an elevated frequency of autoimmune disorders has been repeatedly associated with vulvar lichen sclerosus.[1, 2] We did not collect a detailed history regarding autoimmune disorders, but no cases or controls had a history of clinically diagnosed important immune-related connective disorders such as systemic lupus erythematosus. Finally, in relation to other disorders, the absence of association with diabetes agreed with the results of a previous case-control study conducted in Britain.[2]

We thank Ms. Maria Nigro and Ms. Judy Baggott for editorial assistance.

Fetal liver length in normal and isoimmunized pregnancies

Alistair B. Roberts, MD, Jennifer M. Mitchell, and Neil S. Pattison, MD
Auckland, New Zealand

The length of the right lobe of the fetal liver was measured by means of ultrasound examined on 53 occasions in 21 isoimmunized pregnancies. Fetal blood samples were taken in all patients within 24 hours. Comparisons were made with 350 measurements of liver length in normal pregnancies. A good correlation was found between liver length and fetal hemoglobin level ($r = 0.794$, $p < 0.001$) and between liver length and reticulocyte count ($r = 0.721$, $p < 0.001$). At the time of first sample, all fetuses with a hemoglobin of <100 gm/L had a liver length that was greater than the ninetieth percentile. Liver length measurement seems to be a useful indicator of the degree of fetal anemia in isoimmunized pregnancies. (Am J Obstet Gynecol 1989;161:42-6.)

Key words: Fetal liver, ultrasound, rhesus

Ultrasound examination now plays a major role in the assessment and management of isoimmunized pregnancies. Many ultrasound signs have been advocated as indicators of fetal anemia. These include the presence of fetal ascites, skin edema, pericardial effusion, the measurement of umbilical vein diameter, abdominal circumference, placental size, amniotic fluid volume, fetal activity, and Doppler studies of the fetal aorta and umbilical vein.[1-4] Overall, the use of ultrasound studies to assess the severity of fetal disease has been disappointing.[4] Most signs only appear in the severely anemic fetus. The correlation between optical density of the amniotic fluid (ΔOD 450 nm) and fetal hemoglobin is also poor, especially before 24 weeks.[5]

Therefore many units rely on determining the severity of fetal anemia by direct measurement of fetal hemoglobin or hematocrit level after a sample of fetal blood is obtained. Specimens of fetal blood are usually obtained by percutaneous umbilical blood sampling under ultrasound guidance.[6] Treatment is then usually instituted with the use of an intravascular transfusion technique[7, 8] or a combined intravascular intraperitoneal approach. However, these are invasive procedures and carry significant risks of fetal loss or increased maternal sensitization and antibody production.[4] There is a need for a noninvasive method of assessing the degree of fetal anemia.

Enlargement of the fetal liver in isoimmunized pregnancies has proved a useful subjective sign of increased fetal liver hemopoiesis. The size of the liver has been measured indirectly by abdominal circumference or diameter. Vintzileos et al.[9] showed that direct measurement of the right lobe of the fetal liver was more useful than abdominal circumference

This study was designed to measure the right lobe of the fetal liver in isoimmunized pregnancies and correlate this measurement with fetal hemoglobin. We felt it was important to have normal fetal liver measurements from 15 weeks' gestation, and for this reason collected fetal liver measurements during normal pregnancies from 15 to 40 weeks.

Patients and methods

Normal patients. Three hundred fifty measurements of fetal liver length were made between 15 and 40 weeks' gestation in 350 patients; measurements were taken as part of a clinically requested ultrasound examination. The women studied had regular menstrual cycles with certain last menstrual periods and a scan done before 20 weeks that agreed with their menstrual dates. Delivery occurred within 2 weeks of the pre-

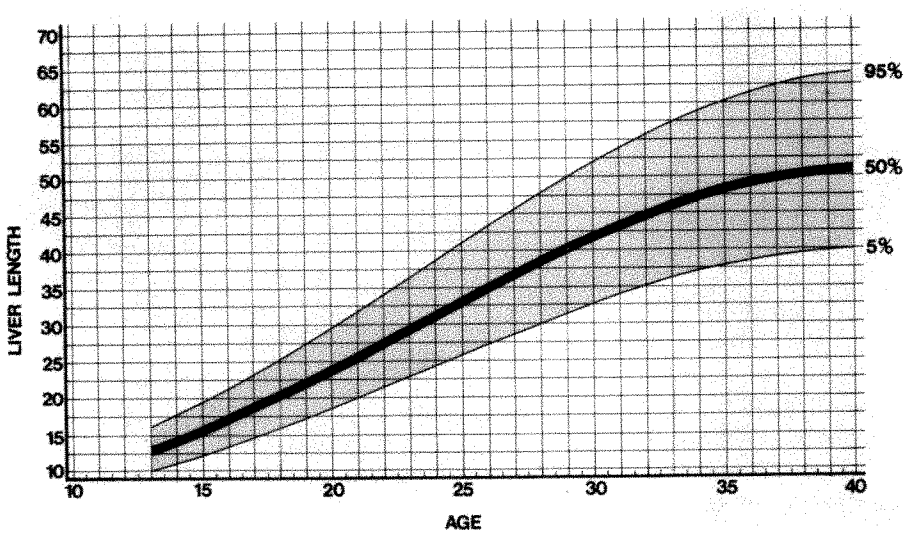

Fig. 2. Relationship between fetal liver length and gestational age in 350 normal pregnancies. Fifth and ninety-fifth percentile confidence limits are indicated.

dicted date of delivery, and neonatal Dubowitz scores were compatible with gestational age.

Fetal liver length was measured by means of the following technique, which is similar to that described by Vintzileos et al.[9] The fetus was scanned until a longitudinal view of the abdominal aorta was achieved. The scanning plane was moved parallel to visualize the right lobe of the liver. The liver was measured from the dome of the right hemidiaphragm to the tip of the right lobe. Fetal position sometimes made it difficult to measure the right lobe, but no particular position of the fetus was selected for exclusion. Ultrasound measurements were made by means of Diasonics sector scanner with a 3.5 or 5 MHz transducer or a Toshiba 100-convex 3.75 MHz transducer. Freeze-frame capability was available and on-screen calipers were used for measurements (Fig. 1). The reproducibility of the measurement was assessed by two independent observers in 29 patients. There was no significant difference between observers ($r = 0.976$, $p < 0.001$). The interobserver variation was less than 10% in 95% of cases.

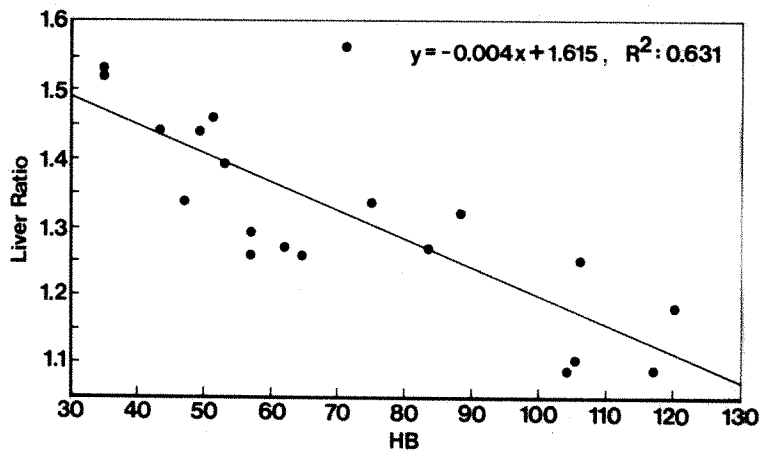

Fig. 3. Relationship between liver length ratio and fetal hemoglobin in 21 patients at time of first sample.

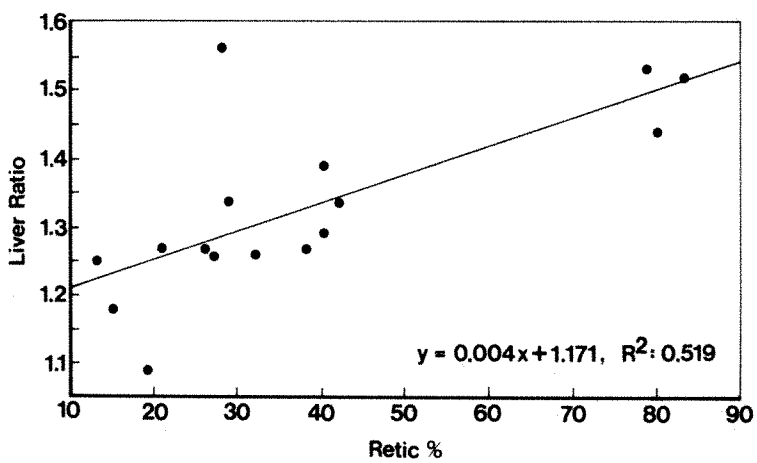

Fig. 4. Relationship between liver length ratio and fetal reticulocyte count at time of first sample.

Isoimmunized pregnancies. Twenty-one pregnant women with severe isoimmunization were studied. The antibodies present were anti-Kell in two women and anti-D in the remainder. Three patients had hydropic fetuses at the time of presentation with gross ascites and significant subcutaneous edema. Patients were referred to the National Women's Hospital after amniocentesis, when the optical density difference (ΔOD 450 nm) was elevated. After detailed ultrasound examination, including measurement of the fetal liver, fetal blood sampling was performed with a 20 cm, 22-gauge needle, directed under ultrasound guidance, into the umbilical vein or artery. The cord was usually sampled within 1 cm of the placental insertion, although occasionally other sites were used, including a free loop of cord or rarely the cord insertion into the fetus. Three milliliters of fetal blood were taken for analysis, including blood grouping. Coombs testing, hemoglobin (urgent), hematocrit, reticulocyte count, Kleihauer, bilirubin, and total protein. Anemic fetuses received a transfusion and fetal blood sampling, and transfusion was repeated at an interval of 1 to 4 weeks. Measurements of fetal liver length were made before fetal blood sampling (within 24 hours) in all 21 patients with the first sample and in 32 subsequent fetal blood samples and transfusions. Fifty-three blood samples in 21 patients were included in the analysis.

For purposes of comparison, liver length is expressed as liver length ratio (actual liver length over mean for gestation).

Results

The relationship between fetal liver length and gestational age is shown in Fig. 2 with fifth and ninety-fifth percentile confidence limits. The predicted limits were obtained by fitting a polynomial regression model for gestational age to a logarithm of liver length and then transforming the resultant prediction intervals

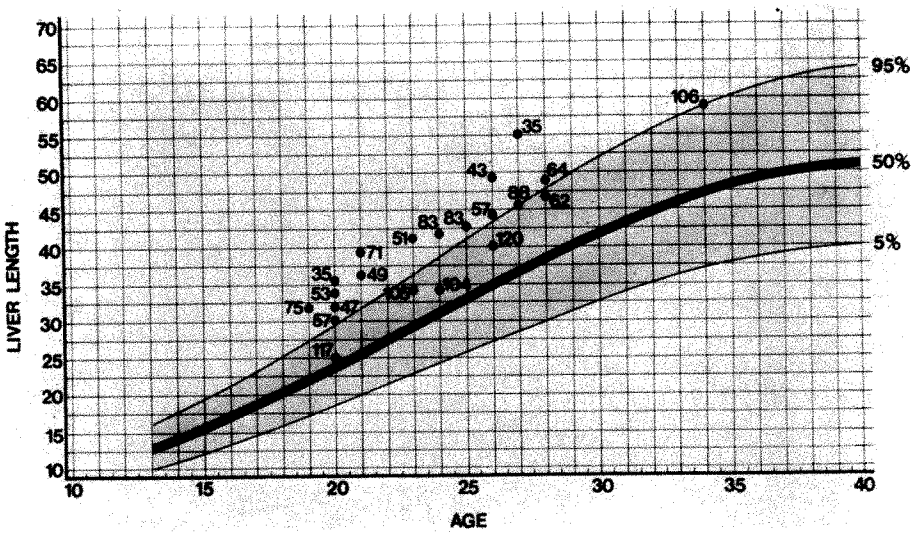

Fig. 5. Actual fetal liver length plotted against normal graph at time of first sample. Numbers beside each point denote fetal hemoglobin.

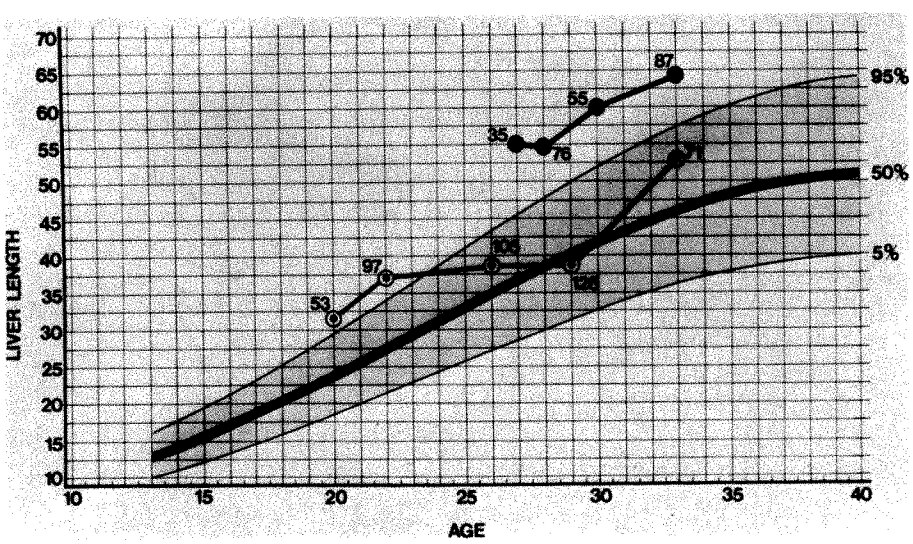

Fig. 6. Actual liver length plotted against normal graph in two cases.

back to the original scale. A quadratic model was found to fit the data well ($R^2 = 0.88$).

Isoimmunized pregnancies. There was a significant relationship ($p < 0.001$) between fetal liver length and fetal hemoglobin level in all 21 patients at the time of first sample ($r = 0.794$) (Fig. 3). There was also a significant relationship ($p < 0.001$) between fetal liver length and the percentage of reticulocytes in the fetal circulation ($r = 0.721$) (Fig. 4). At the time of subsequent transfusion, the relationship between liver length and hemoglobin was significant ($r = 0.631, p < 0.001$), although the relationship with the reticulocyte count was less good ($r = 0.445, p < 0.004$). At the time of the first fetal blood sample, all fetuses with a fetal hemoglobin level of <100 gm/L had a liver length greater than the ninetieth percentile (Fig. 5). Fetal transfusion and correction of fetal anemia led to a relative reduction in fetal liver length (Fig. 6). No difference was found between pregnancies with Kell and D antibodies.

Comment

Fetal liver length measurements in normal pregnancies in this series confirm the data of Vintzileos et al.[9] and more recently those of Murao et al.[10] There is a discrepancy between our data and those of Vintzileos et al. before 24 weeks, which is probably explained by the small numbers that Vintzileos et al. had at the lower gestational age. Our study confirms the usefulness of

liver length in the evaluation of the isoimmunized pregnancy. The study enlarges on the data from Vintzileos et al. by directly comparing liver length with fetal hemoglobin level and reticulocyte count. This has obvious significance for triggering referrals to centers that perform fetal blood sampling and transfusion. This is a particular problem in New Zealand where patients are referred from a long distance and there is a need for a specific measurement or sign that can be used for referral. We currently use amniocentesis, and an optical density of greater than 0.2 is used to trigger referrals. However, the correlation between fetal hemoglobin and optical density is poor.[5] It is now possible to suggest that any fetal liver measurement greater than the ninetieth percentile in a patient with antibodies should be considered for transfer. Confusion may arise, since there are other reasons for enlargement of the fetal liver. Some fetuses of pregnant women with diabetes have significantly enlarged livers, although this is usually in the third trimester. Other possibilities include fetal or maternal infections or fetal anemia from other causes. It will probably be most useful before 30 weeks of gestation when it is rare to have fetal liver enlargement for other reasons. It is difficult to be sure how reproducible measurement of fetal liver length will be. We tested the reproducibility between two experienced observers on the same patient with no knowledge of the others results. The reproducibility was good. The reproducibility of the measurement depends on the experience of the operator and more important on the ultrasound equipment used. The improvements in ultrasound technology have made visualization of the fetal liver possible. Variations in quality of equipment will undoubtedly lead to problems with reproducibility. The position of the fetus can also be a problem. If the right lobe of the fetal liver is posterior, it can be difficult to identify the tip of the right lobe.

Measurement of the size of the fetal liver seems to be more useful before the first transfusion than subsequently, and this may be partly gestation dependent. The percentage of hemopoesis that is extramedullary decreases with gestational age, and it is probable that switching to increased extramedullary hemopoesis may occur later with increasing gestational age. Therefore, liver length measurement may be more useful before 30 weeks, although it is our experience that even in the third trimester, a liver size that is well within the normal range has not so far been associated with any significant anemia.

In conclusion, our studies confirm the usefulness of measuring fetal liver length in the assessment of isoimmunized pregnancies. Further studies are needed to test whether the measurement is reproducible enough to be useful on a larger scale.

We thank Professor A. Scott, Statistics Department, Auckland University, for help with the statistical analysis.

Does midtrimester ΔOD_{450} of amniotic fluid reflect severity of Rh disease?

Uma Ananth, MD, and John T. Queenan, MD
Washington, D.C.

Thirty-two patients with Rh-immunized pregnancies had amniocenteses between 16 and 20 weeks' gestation. Serial amniotic fluid values of delta optical density at 450 nm were studied to predict the severity of Rh disease. A value >0.15 indicated severe Rh immunization. Values <0.09 indicated mild or no Rh disease; delta optical density at 450 nm between 0.09 and 0.15 require further evaluation to determine the trend. Midtrimester amniocentesis is a simple technique that helps to determine which patients may or may not require fetal blood sampling. (Am J Obstet Gynecol 1989;161:47-9.)

Key words: Midtrimester, amniotic fluid analysis, ΔOD_{450}, Rh immunization

Erythroblastosis fetalis that occurs as a result of Rh immunization continues to be a significant contributor to perinatal mortality despite the widespread use of Rh-immune globulin. Before Liley's[1] systematized approach to management of the Rh problem by serial amniotic fluid values of delta optical density measurements at 450 nm (ΔOD_{450}), 25% of all Rh-immunized pregnancies were lost. Preterm delivery to avoid intrauterine death was the principal method of management. Many Rh-positive fetuses died in utero as a result of erythroblastosis fetalis and others died in the nursery. Some Rh-negative babies died because of prematurity when they were delivered early unnecessarily. Amniotic fluid analysis allows determination of the severity of Rh disease in utero and thus permits intrauterine transfusion or delivery of the affected fetus before death occurs in utero and allows the unaffected fetuses to remain in utero to gain valuable maturity. The Liley approach is extremely effective in preventing fetal death in the third trimester.[2, 3]

In cases of very severe Rh immunization, fetal death can occur in the second trimester. Because intrauterine intravascular fetal transfusion is capable of saving fetuses in the early second trimester, it is important to evaluate the reliability of amniotic fluid ΔOD_{450} in predicting fetal condition in the second trimester. Therefore, this study was undertaken to determine whether the amniotic fluid ΔOD_{450} value reflects the severity of Rh disease in the early second trimester and thereby indicates the need for intrauterine transfusion.

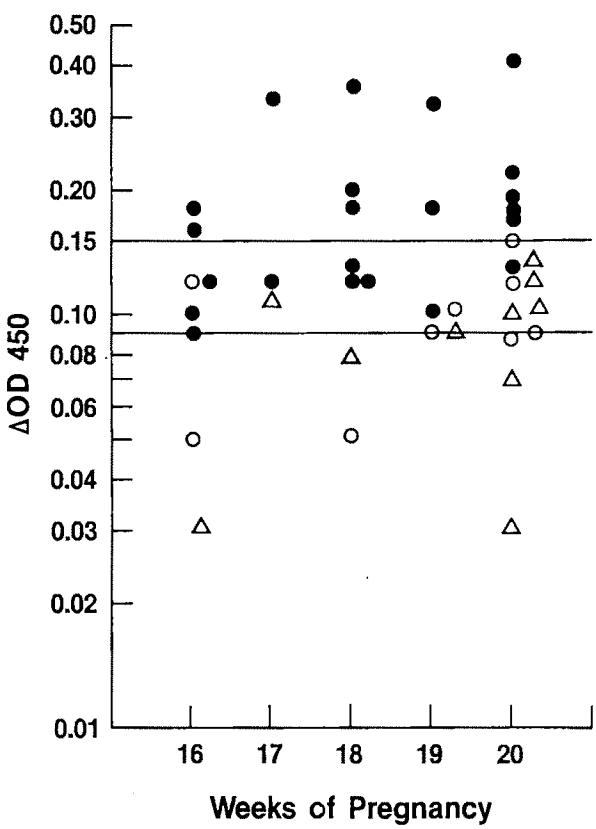

Fig. 1. Distribution of amniotic fluid ΔOD_{450} values from Rh-immunized pregnancies between 16 and 20 weeks' gestation. ○, Unaffected pregnancies; △, mildly affected pregnancies; ●, severely affected pregnancies.

Material and methods

Thirty-two patients with Rh immunization who were between 16 and 20 weeks' gestation at the time of initial amniocentesis were studied. The criteria for selection included a maternal antibody titer ≥1:64 or a history of previous stillbirth. Study patients were healthy

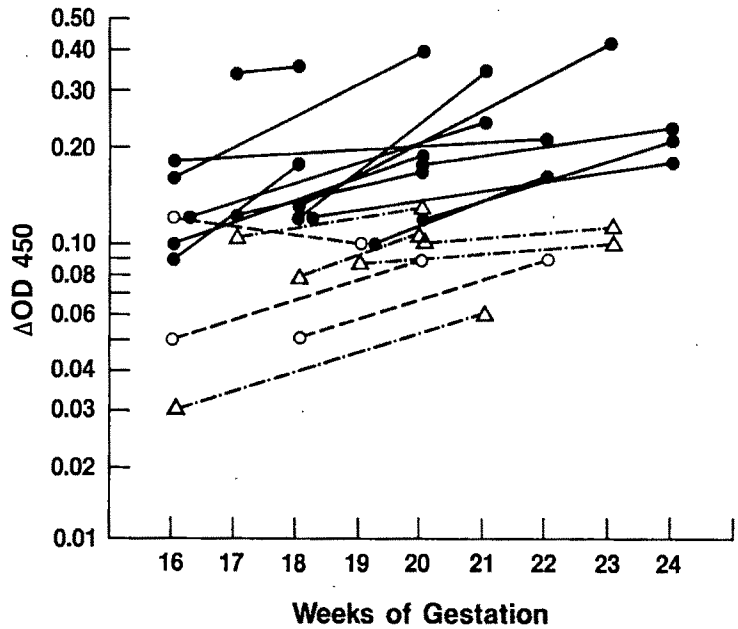

Fig. 2. Trend of amniotic fluid ΔOD_{450} values.

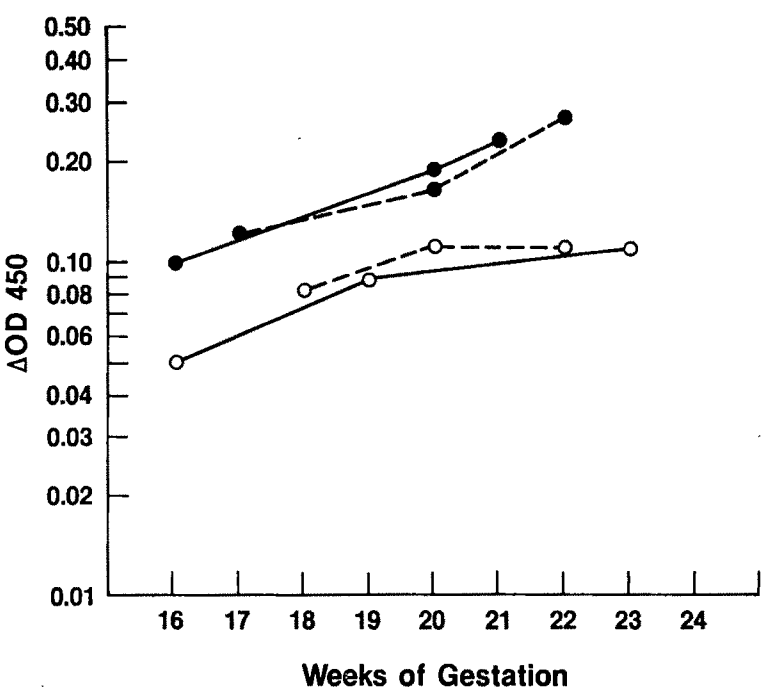

Fig. 3. Serial amniotic fluid ΔOD_{450} values in two patients in their two consecutive pregnancies. *Continuous* and *interrupted lines* represent different patients.

women between 30 and 40 years of age who had amniocenteses for genetic purposes or for determining amniotic fluid ΔOD_{450}.

Each sample of amniotic fluid was centrifuged at 3000 rpm for 10 minutes immediately after collection, and samples were then analyzed in a spectrophotometer to obtain a continuous recording between 300 and 700 nm. The deviation in optical density (ΔOD) was obtained by drawing an arbitrary line between 375 and 525 nm and measuring the difference at 450 nm, as described by Liley.[1,2] Samples demonstrating significant peaks at 412, 540, and 575 nm were excluded

from the study because they indicated contamination from other heme pigments and could have altered the bilirubin curve.[4] Twenty-one of the 32 patients underwent a second amniocentesis 1 to 6 weeks after the first examination and were studied to examine the trend of ΔOD_{450} values. Two of the patients were pregnant twice during the period of our study and are discussed here.

Results

Fig. 1 shows the distribution of 41 ΔOD_{450} values obtained from the 32 patients studied between 16 and 20 weeks' gestation. The values were divided into three groups based on the outcome. Group 1 consisted of unaffected pregnancies; these patients were delivered of Rh-negative babies. Group 2 comprised mildly affected pregnancies, defined in our study as fetuses who were delivered at term, possibly requiring phototherapy but no exchange transfusions. Group 3 included severely Rh-immunized pregnancies, defined as fetal death, or infants who required intrauterine transfusions or exchange transfusions.

It is evident from Fig. 1 that the amniotic fluid ΔOD_{450} values for groups 1 and 2 are evenly distributed between 0.03 and 0.15. For group 3, all values lie above 0.08. Therefore, there is an area of overlap between 0.09 and 0.15 in which all three groups are represented.

Fig. 2 shows the trend of ΔOD_{450} values in the 21 patients who underwent repeat amniocenteses between 1 and 6 weeks after the first examination. The values for all three groups of patients show an upward trend.

Fig. 3 illustrates the trend in ΔOD_{450} values for the two patients who were pregnant twice during the study. In their first pregnancies, the serial ΔOD_{450} values showed an upward trend, rising above the critical value of 0.15. Both first pregnancies ended in fetal death in the second trimester. Their subsequent pregnancies resulted in healthy Rh-negative babies, reflected by serial ΔOD_{450} values <0.09.

Comment

We have previously established[5] normal values of ΔOD_{450} in the early trimester and have shown that the values are distributed between 0.01 and 0.15, with a slight but statistically significant upward trend from 16 to 20 weeks' gestation.[5] The findings in this study concur with those of our earlier study since a similar upward trend is demonstrated (Fig. 2).

The normal values for ΔOD_{450} in the third trimester show a downward trend from the twenty-seventh week until term. This trend forms the basis for the management of Rh disease in the third trimester. The accuracy of predicting severe Rh disease from a value in the third trimester is excellent.[3] However, it has been shown that Liley's graph cannot be extrapolated into the second trimester.[5, 6] Investigators[6] have demonstrated a poor correlation between amniotic fluid ΔOD_{450} values and fetal hemoglobin in the midtrimester. This has led them to conclude that amniotic fluid ΔOD_{450} has no predictive value in the second trimester. Therefore they advocated the routine use of percutaneous umbilical blood sampling in all Rh-immunized pregnancies. From a clinical standpoint the controversial issues are: (1) Can a single amniotic fluid ΔOD_{450} value or serial values predict which fetus has severe Rh disease early enough for fetal transfusion to be effective? (2) Can amniotic fluid ΔOD_{450} predict which fetuses have mild or no disease so that fetal umbilical blood sampling and intrauterine transfusions are not necessary?

From this study it is clear that a single amniotic fluid ΔOD_{450} value >0.15 or an amniotic fluid trend rising above 0.15 indicates severe disease. These patients can be selected for percutaneous umbilical blood sampling to confirm the degree of fetal anemia and whether direct intravascular transfusion is indicated. Values <0.09 indicate unaffected or mildly affected fetuses. These fetuses require further evaluation with serial amniocentesis to verify the trend. In cases in which the values fall between 0.09 to 0.15, careful follow-up with serial amniotic fluid ΔOD_{450} values is required to establish the amniotic fluid trend that determines the severity of Rh disease.

This relatively simple technique allows the identification of fetuses that need intravascular transfusion and avoids performing the more invasive procedure of percutaneous umbilical blood sampling on a routine basis.

Increased frequency of detection of human papillomavirus deoxyribonucleic acid in exfoliated cervical cells during pregnancy

Robert F. Rando, PhD,[a, b] Steven Lindheim, MD,[b] Lisa Hasty, MD,[b] Thomas V. Sedlacek, MD,[b] Mark Woodland, MD,[b] and Catherine Eder, BA[a]

Philadelphia, Pennsylvania

Exfoliated cells of the uterine cervix obtained from women during pregnancy and at the time of their first postpartum examination were used to monitor the prevalence of human papillomavirus infections in this population and to study the natural fluctuations in viral expression. When deoxyribonucleic acid hybridization analysis alone was used to monitor the presence of human papillomavirus infection, 20.9% of our study population had results that were positive for human papillomavirus deoxyribonucleic acid during their first-trimester examinations. A dramatic increase in the percentage of women with positive results for human papillomavirus deoxyribonucleic acid was observed at the time of the patients' third-trimester examinations (46%). The overall increase in human papillomavirus-positive patients was a combination of a small number of patients who had positive results on their first examination and negative results on their second examination, and a larger number of patients who had negative results on their first-trimester examination and positive results for human papillomavirus deoxyribonucleic acid in the exfoliated cervical cells at the time of their third-trimester examination. The total percentage of patients with positive results for human papillomavirus deoxyribonucleic acid in their cervical cells at one or both assay points during pregnancy was 52.5%. Samples obtained at the postpartum examination demonstrated a dramatic decrease in the number of samples positive for human papillomavirus deoxyribonucleic acid (17.5%). This result was a combination of a large decrease in human papillomavirus-positive patients coupled with a small increase in detectable levels of human papillomavirus deoxyribonucleic acid in cervical samples from patients who had negative results on their previous examination. This study demonstrates a very high level of detectable human papillomavirus deoxyribonucleic acid in exfoliated cervical cells obtained during pregnancy and shows that the detectable levels of human papillomavirus deoxyribonucleic acid fluctuate during pregnancy. (AM J OBSTET GYNECOL 1989;161:50-5.)

Key words: Human papillomavirus (HPV), deoxyribonucleic acid (DNA), uterine cervix, pregnancy, hybridization

Surveillance of reported cases of clinically apparent anogenital human papillomavirus (HPV) infections indicated a steady rise in the incidence of new cases between 1966 to 1983.[1] In 1976 Meisels and Fortin[2] helped to heighten interest in human papillomaviruses when they reinterpreted the morphologic features of dysplasia of the uterine cervix as manifestations of HPV infections. Interest was further stimulated when HPV deoxyribonucleic acid (DNA) was identified in premalignant and malignant anogenital lesions.[3] To date more than 50 distinct types of HPVs have been described. At least 12 distinct types have been detected in anogenital tract and oral cavity lesions. Several studies have reported that HPV type 16 and HPV type 18 are found in association with a majority of high-grade dysplastic lesions of the cervix, carcinoma in situ, and cervical carcinomas.[3]

Two recent studies estimated that 10% to 20% of random populations that had cytologically "normal" cervices were in fact infected with HPV.[4, 5] Burk et al.[6] detected HPV DNA in 29% of a population of women who were referred to a colposcopy clinic and had normal Papanicolaou smears. Wickenden et al.[7] detected HPV infections in 10.5% of a population from a sexually transmitted disease clinic who had cytologically normal cervices. It is interesting that a study conducted among pregnant women[8] detected HPV DNA in 28% of the study population.

The enhanced detection of viral infections has been reported in patients with impaired cell-mediated immunity.[9, 10] It has also been noted that HPV infections and HPV-associated neoplasia of the anogenital tract

From the Departments of Pathology[a] and Obstetrics and Gynecology,[b] Pennsylvania Hospital.

Received for publication July 22, 1988; revised October 9, 1988; accepted January 10, 1989.

Reprint requests: Robert F. Rando, PhD, Department of Pathology, Preston Bldg., Rm. 758, Pennsylvania Hospital, 8th and Spruce St., Philadelphia, PA 19107.

are more readily detected in immunodeficient patients than in the general population.[9, 10] During pregnancy, a natural altered or depressed immunologic state has been suggested.[8] It has also been reported that clinically apparent HPV infections of the female genital tract seem to occur more frequently during pregnancy and regress rapidly after delivery.[11] Schneider et al.[8] reported the detection of HPV DNA in exfoliated cervical cells in 28% of a pregnant population compared with 12.5% for nonpregnant control patients; a higher detection level occurred in samples obtained later in pregnancy.

In addition to an immunodepressed condition, hormonal effects during pregnancy may play a role in the enhancement of viral infection or expression. Long-term users of oral contraceptives show an increased risk for the development of HPV-associated neoplasia.[12, 13] There are also reports of hormonal stimulation of HPV-directed transcription in vitro[14] and proliferation of viral growth with β-estradiol in vivo (Krieder J, personal communication).

This article describes a prospective study designed to evaluate the basal level of cervical HPV infections in a population of pregnant women, and to determine whether there are fluctuations in the detectable levels of HPV DNA over the course of pregnancies through the first postpartum examination.

Material and methods

Sample collections. From April 1987 until August 1987 all new patients at Pennsylvania Hospital's obstetric clinic were recruited for this study. This population of women was young (mean age = 23.45 years), sexually active, and from a low socioeconomic group. At the time of the patient's first-trimester examination, a sample of exfoliated cervical cells was obtained and used for both cytologic and DNA hybridization analysis. Similar specimens of exfoliated cervical cells were obtained for DNA hybridization analysis during a third-trimester visit (28 to 34 weeks) and at the time of the patient's first postpartum checkup (no later than 6 weeks after delivery).

DNA extraction. Exfoliated cervical cells were suspended in phosphate-buffered saline solution, concentrated by low-speed centrifugation (1500 rpm), resuspended in 1 ml of cell lysis buffer (10 mmol/L Tris hydrochloride, pH 8.0, 0.6% sodium dodecyl sulfate, 10 mmol/L ethylenediaminetetraacetic acid). Ribonuclease A (10 μg/ml) and proteinase K (50 μg/ml) were added to the cell lysis buffer and the samples were incubated at 37° C for 2 hours. Total cellular DNA was purified by extracting the lysed cellular material twice with an equal volume of phenol/chloroform/isoamyl alcohol (25:24:1). The extracted nucleic acids were then precipitated by adjusting the salt concentration to 0.3 mol/L sodium acetate and adding 2.5 volumes of cold (−20° C) ethanol. The DNA was concentrated by centrifugation, washed twice with 70% ethanol, dried under vacuum, resuspended in 1 ml of a buffer containing 10 mmol/L Tris hydrochloride (pH 7.5) and 1

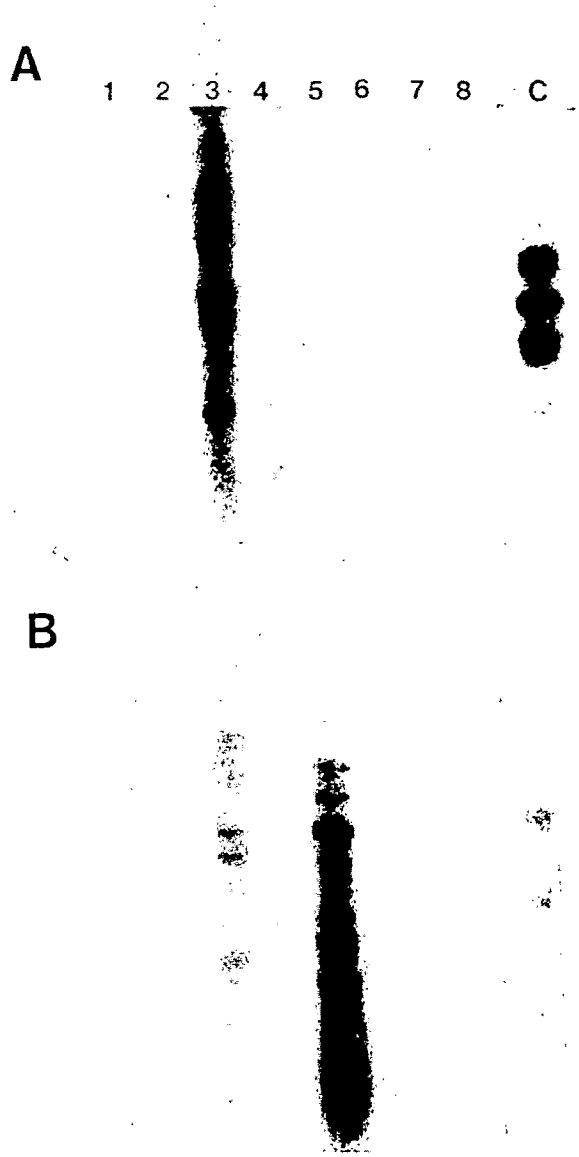

Fig. 1. Detection of HPV DNA in samples obtained from exfoliated cervical cells by Southern blot hybridization. DNA was extracted, cleaved with restriction enzymes, electrophoresed, and transferred onto nylon filter membranes as described in "Material and methods." The procedure described was performed in triplicate. One of each of the three triplicate filters was hybridized with a combination of ^{32}P-labeled molecular probes corresponding to HPV-16/18 (**A**) or HPV-31/33/35 (data not shown) or HPV-6/11 (**B**). DNA extracted from the samples analyzed in lane *3* hybridized better with the HPV-16/18 probes. DNA extracted from the sample in lane *5* hybridized better with the HPV-6/11 probes. Lane **C** contained 20 pg of an HPV-16 recombinant clone that was cleaved with *Pst* I.

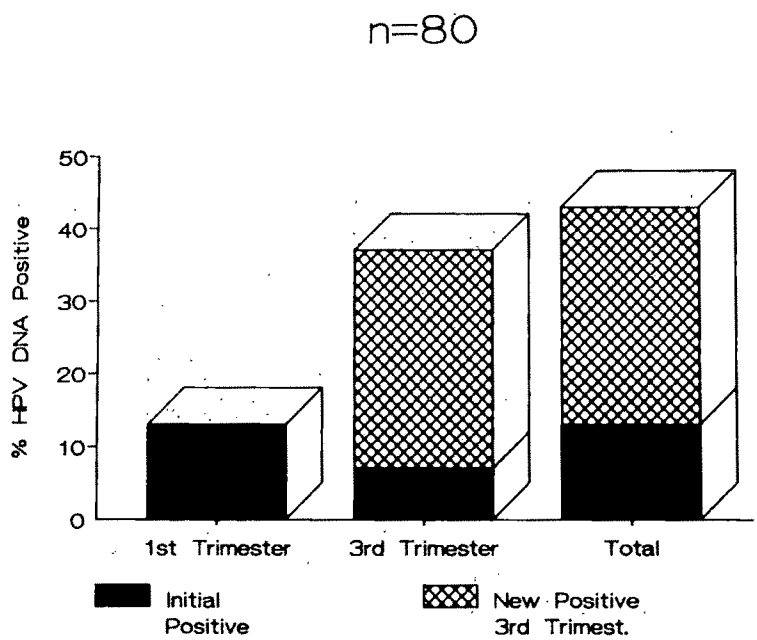

Fig. 2. Graphic representation of HPV-positive cervical samples obtained from patients compliant through their third-trimester examination. The number of patients with positive results in the third trimester is a combination of patients who had positive results in the first trimester (minus those patients who had positive results at their first-trimester examination but negative results for HPV DNA in their cervical cells during their third-trimester examination) combined with the number of new patients with negative results in the first trimester but who had HPV detected during their third-trimester examination. The *bar* labeled *total* represents patients who were HPV DNA-positive in one or both of their examinations.

Table I. Correlation of Papanicolaou smear versus DNA hybridization analysis for the detection of HPV during first trimester of pregnancy

DNA neg.	8	79	87
TOTAL	14	96	110

*Papanicolaou-positive smears included those described as condylomatous, hyperkeratosis, parakeratosis, or squamous atypia.

†Fourteen patients were classified as having benign atypia. Of those 14 patients, 5 had positive results for HPV DNA.

mmol/L ethylenediaminetetraacetic acid; the concentration was determined by spectrophotometric analysis at 260 nm.

Hybridization analysis. Total DNA (10 to 15 μg) extracted from patient samples was cleaved with the restriction endonuclease *Pst* I as recommended by the manufacturer (New England Biolabs). The resulting DNA fragments were fractionated by electrophoresis in a 0.8% agarose gel and then transferred to nylon filter membranes (Amersham Hybond-N). DNA hybridization analysis was performed with modifications of the Southern blot technique as previously described.[15] Molecular probes corresponding to HPV types 6, 11, 16, 18, 31, 33, and 35 were amplified and purified using standard laboratory methods.[16] The HPV genomes were purified from flanking bacterial plasmid DNA and then radiolabeled with ^{32}P-deoxycytidine triphosphate.[15, 16]

Results

Exfoliated cervical cells obtained during the first-trimester examination from 110 patients were examined by cytologic and DNA hybridization analysis for the presence of HPV infection. A comparison of the Papanicolaou smear and DNA hybridization analysis for the detection of HPV is described in Table I.

Thirty-one of the 110 patients (28.2%) had positive results for the presence of HPV in their cervical cells. Of these 31 HPV-positive patients, eight (7.2%) had positive results by Papanicolaou smears alone, six (5.4%) had positive results by both criteria, and 17 (15.4%) had only positive hybridization analysis results (Table I). A total of 23 of 110 (20.9%) had positive DNA hybridization analysis results.

DNA hybridization analysis was performed in triplicate for the first-trimester patient samples. The tripli-

*Any patient who had HPV DNA detected during their first-trimester, third-trimester, or both examinations were considered HPV DNA pos.

cate hybridization reactions used mixtures of HPV types 16 and 18, HPV types 31, 33, and 35, or HPV types 6 and 11 for molecular probes (Fig. 1). Of the 23 patient samples that contained HPV DNA at the first-trimester examination, HPV-16/18 was detected in 14 (60.8%) samples, HPV-31/33/35 was detected in six (26%), and HPV-6/11 was detected in one (4.3%) sample. In the remaining two samples (8.7%), HPV DNA was detected but not typable with the available molecular probes.

Samples of exfoliated cervical cells were obtained from 80 of the original 110 patients during their third trimester-visit. Thirteen of these 80 patients (16.2%) had positive HPV DNA results during their first-trimester examination. DNA hybridization analysis was performed on these samples. The results indicate an increase in the percentage of patients with positive results for HPV DNA in the third trimester, compared with the first-trimester results (Fig. 2). This increase was reflected in a moderate regression of detectable levels of HPV DNA in patients with positive results for HPV DNA during the first-trimester visit and negative results at the third-trimester visit (7.5%), coupled with a large increase of patients with negative results for HPV DNA during the first trimester and positive results at the third trimester (37.5%). The total number of patients with positive HPV DNA results during their third-trimester of pregnancy was 37 of 80 (46.2%). The total number of patients who had positive results for HPV DNA at either or both examinations was 43 of 80 (53.7%). No significant correlation was observed when information concerning the smoking habits (obtained from 64 patients who remained compliant through their third-trimester examination) was compared with the presence of HPV DNA in the patients cervical cells (data not shown). In addition, information concerning the number of sexual partners (obtained from 66 patients compliant through the third trimester) was compared with the detection of HPV DNA in the patients

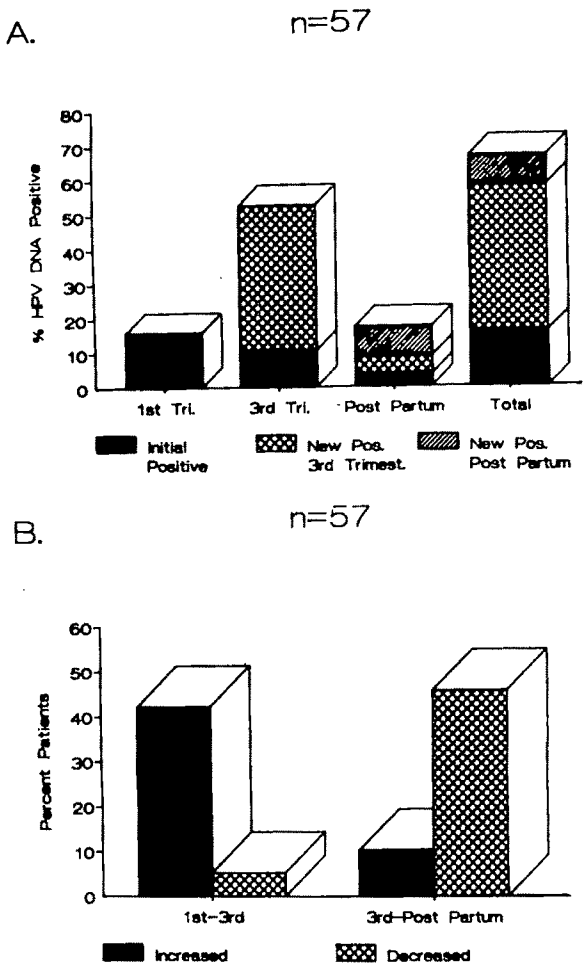

Fig. 3. Graphic representation of HPV DNA analysis for those patients who were compliant through their postpartum examination. The total percentage of patients positive at the three assay points is depicted in the top panel **(A)**. The percentage of patients who changed with respect to the detection of HPV DNA in their cervical cells from first to third trimester or from third trimester to postpartum examinations is depicted in the bottom panel **(B)**.

cervical cells (Table II). No significant difference was observed between patients who reported having one or two sexual partners compared with those who reported more than two partners and the detection of HPV DNA in the patients cervical cells.

Exfoliated cervical cells were obtained from 57 patients who remained compliant through their first postpartum examination (Fig. 3). DNA hybridization results indicate a decrease in the number of patients with detectable HPV infections between the third trimester of pregnancy and the first postpartum examination. The observed decrease was a combination of a small increase (10.2%) of HPV-positive patients between the third trimester and first postpartum examination coupled with a large decrease (45.6%) over this same time period. The total percentage of patients with positive

results at the time of their postpartum examination was 17.5%; 66% of patients had positive results at one of the three assay points.

Comment

Use of DNA hybridization (Southern blot) analysis as a diagnostic tool has confirmed the observations of several recent studies[1, 2, 3] that routine cytologic examination alone will not detect all types of cervical HPV infections. However, neither will DNA hybridization analysis alone detect all HPV infections. A significant number of patients (eight of 110, or 7.2%) with cytologically abnormal features consistent with HPV infection did not have HPV detected by DNA hybridization analysis in the first trimester.

The HPV infection level detected with DNA hybridization criteria alone for samples obtained during the first trimester (23 of 110 or 20.9%) was lower than the infection level of 29% reported for a population that was cytologically normal but referred to a colposcopy clinic,[6] and much higher than the level of 10.5% reported for women with normal cytologic and colposcopic examinations in a sexually transmitted disease clinic.[7] This level was also lower than the level reported by Schneider et al.[8] for a general population of pregnant women (28%). The difference between the first-trimester examination results reported here (Table I) and the 28% reported by Schneider et al.[8] could be a result of differences in the population size, the sensitivities of the different assay techniques used, the nature of the Pennsylvania Hospital clinic population, and the period during pregnancy at which samples were obtained.

Of the 80 patients who were compliant until their third-trimester examination, 37 (46.2%) had positive results for cervical HPV infection and 42 (52.5%) had positive HPV DNA results in one or both of their analyzed samples (Fig. 2). It has been reported that detection of HPV DNA is greater in cervical samples obtained later in pregnancy than in those obtained in the early stages.[8] In addition to the large progression in the number of HPV DNA-positive patients from the first to the third trimester, there was a concomitant decrease of detectable HPV DNA levels (6.2%) in the study population. It is possible that experimental error accounted for some of the samples that changed categories over time, but the number of cases that did change indicates that a certain level of natural fluctuation in viral expression occurs in these patients.

The observed decrease in detection of HPV DNA in the samples obtained from patients during their postpartum examinations (Fig. 3) reflects a difference in detectable levels of HPV DNA in the pregnant and nonpregnant cervical samples. We cannot determine from this study whether the difference in detectable levels of HPV DNA was a result of a higher number of HPV-infected cells during pregnancy or a higher level of viral DNA per infected cell. The increase in detection during pregnancy could represent an increase in viral expression in response to host immunosuppression during pregnancy, or to changes in the hormonal melieu bathing the epithelial cells of the cervix during pregnancy, or both. It has been reported that regulatory elements on the viral genome are responsive to cellular factors[17] and to glucocorticoid hormones in vitro.[14] It also has been observed that β-estradiol can stimulate the growth of experimental condylomas induced with HPV-11 in nude mice (Krieder J, personal communication).

Obvious fluctuations of the HPV status in maternal epithelial cells were noted in this study. The regression and progression patterns, although not well defined, appear to correlate with the natural immunologic and hormonal environment of the pregnant and postpartum patient. The actual percentage of the population infected with anogenital HPVs could be much higher than described in other studies of nonpregnant women. Further studies are needed to elucidate the natural history and true prevalence of anogenital HPV infections.

We thank J. C. Cohn (Pennsylvania Hospital, Department of Orthopedics) and K. Kushner (Pennsylvania Hospital, Department of Pathology) for assistance with data analysis and presentation. We also thank R. Unger (Hospital of the University of Pennsylvania, Department of Obstetrics and Gynecology) for critically reviewing this manuscript, and Microprobe Corp. of Bothell, Wash., for providing HPV-33 and HPV-35 molecular probes.

Mechanism for human papillomavirus transmission at birth

Thomas V. Sedlacek, MD,[a] Steven Lindheim, MD,[a] Catherine Eder, BA,[b] Lisa Hasty, MD,[a] Mark Woodland, MD,[a] Avi Ludomirsky, MD,[a] and Robert F. Rando, PhD[a, b]

Philadephia, Pennsylvania

We attempted to investigate mechanisms, in addition to sexual contact, by which human papillomaviruses associated with anogenital tract lesions could be transmitted. Samples of exfoliated cervical cells were obtained from 45 pregnant women and were assayed by Southern blot hybridization analysis for the presence of human papillomavirus nucleic acids. Twenty-five of the 45 women had cells positive for human papillomavirus deoxyribonucleic acid. A neonatal nasopharyngeal aspirate was obtained at term and analyzed for the presence of human papillomavirus deoxyribonucleic acid. We documented the presence of human papillomavirus deoxyribonucleic acid in the oral pharyngeal cavity of the neonates in 15 of 45 nasopharyngeal samples analyzed. Amniotic fluid was obtained from 13 patients when their membranes were artificially ruptured. These samples were assayed for the presence of human papillomavirus deoxyribonucleic acid; two of the 13 amniotic fluid samples contained human papillomavirus deoxyribonucleic acid. The detection of human papillomavirus deoxyribonucleic acid in the oral cavity of neonates is indicative of a perinatal mechanism of viral transmission. The detection of human papillomavirus deoxyribonucleic acid in the amniotic fluid may suggest an in utero mechanism of transmission. However, problems encountered in collecting the amniotic fluid samples preclude us from definitive interpretation of these data. (Am J Obstet Gynecol 1989;161:55-9.)

Key words: Human papillomavirus (HPV), deoxyribonucleic acid (DNA), uterine cervix, pregnancy, hybridization

Several different human papillomavirus (HPV) types have been identified in benign[1-3] and malignant[4, 5] lesions of the respiratory tract. One of the easiest HPV-induced lesions to identify is laryngeal papillomatosis. Benign laryngeal papillomatosis can lead to hoarseness and progressive enlargement that results in obstruction of the airway.[6] In the majority of cases, papillomatous growths in the respiratory tract can be controlled with a limited number of ablative procedures. However, in some instances the papillomas in the larynx rapidly regrow after apparent complete surgical excision.

In juvenile-onset laryngeal papillomatosis (clinical onset before puberty), 75% of cases are diagnosed before 5 years of age.[6] Several laboratories have established the causative relationship between human papillomaviruses (HPVs) [especially HPV type 6 (HPV-6) and HPV type 11 (HPV-11)] and respiratory papillo-

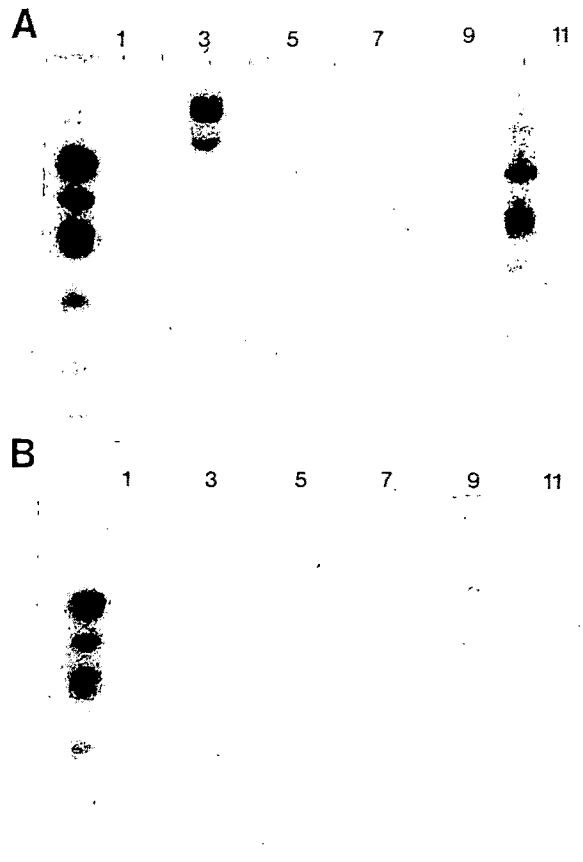

Fig. 1. Detection of HPV-DNA in samples obtained from exfoliated cervical cells, nasopharyngeal aspirates, and amniotic fluid by Southern blot hybridization. DNA was extracted, cleaved with the restriction endonuclease *Pst* I, and transferred onto nylon filter membranes as described in "Material and methods." The filters were hybridized with a mixture of ^{32}P-labeled HPV DNAs. The mixture included HPV types 6,11, 16,18, 31, 33, and 35. Examples of hybridization results obtained for sample DNA (10 to 15 μg) extracted from exfoliated cervical cells (lanes *1* to *5*) and from nasopharyngeal aspirates (lanes *6* to *11*) are shown in the *top panel* **(A).** Lanes *3* and *10* in the *top panel* contain DNA sequences that hybridize with the ^{32}P-labeled molecular probes. The *bottom panel* **(B)** contains total DNA extracted from amniotic fluid (lanes *1* to *11*). Lane *8* in the *bottom panel* contains DNA sequences that hybridize (faintly) with the ^{32}P-labeled molecular probes. The left-hand unmarked lane, in both the top and bottom panels, contains 20 pg of a recombinant HPV-16 genome digested with *Pst* I.

matosis.[7,8] HPV-6 and HPV-11 are also associated with the majority of exophytic genital condylomas.[9] Mounts and Kashima[10] correlated specific subtypes of HPV-6 with extent and severity of disease; HPV-6c was present in all patients with disease extension into the trachea and lungs. It has been reported that HPV genomes can be found in histologically "normal" epithelium adjacent to (in some cases several centimeters away from) the papillomatous lesion.[11,12] This observation may explain the lateral spread of the lesions to previously uninvolved sites, including extension into the trachea and the rapid recurrence in some cases after surgical removal. Factors to help predict a clinical course have yet to be established.

Despite the recent accumulation of information concerning anogenital tract HPV infections, including the prevalence and association with anogenital malignancies.[13] little is known about the natural history of HPV infections. However, alternate mechanisms of transmission may also exist that would explain the fact that the HPV types found in adult genital warts are also found in juvenile-onset laryngeal papillomatosis. The possibility that the HPV infection in patients with juvenile-onset laryngeal papillomatosis is acquired by the newborn during its passage through an HPV-infected birth canal was suggested in 1953 by Webb[14] and again in 1956 by Hajek.[15] A recent study observed that a history of maternal condyloma could be elicited in over 30% of mothers bearing children with these lesions.[16] To date, no prospective study exists to document transmission during the birth process. It is very likely that the virus is transmitted intrapartum as the fetus passes through infected secretions of the birth canal. However, one case of juvenile-onset laryngeal papillomatosis has been documented from a nonruptured elective cesarean section, suggesting that additional mechanisms of transmission may exist.[10]

A prospective study was undertaken at the obstetric clinic of Pennsylvania Hospital to elucidate mechanisms by which neonates can become infected with HPV, and to give further insight into the natural history of this virus.

Material and methods

From April 1987 through August 1987 all new prenatal patients at Pennsylvania Hospital's obstetric clinic were solicited for and subsequently enrolled in this study. The population of women was young (mean age = 22.4 years), sexually active, and from a low socioeconomic group. During their initial first-trimester visit, a sample of exfoliated cervical cells was obtained for cytologic and deoxyribonucleic acid (DNA) hybridization analysis. During the third-trimester visit (between 28 and 34 weeks), a second specimen of exfoliated cervical cells was obtained for DNA hybridization analysis.

Patients with intact membranes who were seen in the labor and delivery suite in active labor had elective artificial rupture of the membranes with an 18-gauge needle. Betadine was used to cleanse the vulva, vagina, and cervix. One patient, who underwent an amniocentesis for fetal maturity at 38 weeks before a repeat cesarean section, had 1 ml of amniotic fluid saved for DNA hybridization analysis.

After delivery nasopharyngeal aspirates from all neo-

Table I. Distribution of HPV types detected in maternal cervical cells

	HPV types

No. detected (n = 25)	0	12	4	9

nates were obtained with a DeLee suction device. The catheter was placed in the oral pharynx to the level of the nasopharynx and then inserted into the nares. The specimens (3 to 5 ml) obtained were analyzed for the presence of HPV DNA.

Patients were excluded from the study if we were unable to obtain matched samples from the maternal cervical cells and from the neonatal nasopharyngeal aspirate.

Nucleic acid extraction. Exfoliated cervical cells were resuspended in phosphate-buffered saline solution, concentrated by low-speed centrifugation (1500 rpm), and resuspended in 1 ml of cell lysis buffer (10 mmol/L Tris hydrochloride, pH 8.0, 0.6% sodium dodecyl sulfate, and 10 mmol/L ethylenediaminetetraacetic acid). Proteinase K (50 μg/ml) and ribonuclease A (10 μg/ml) were added to the cell lysis buffer and the cell samples were incubated for 2 hours at 37° C. DNA was purified by extracting the samples twice with an equal volume of phenol/chloroform/isoamyl alcohol (25:24:1). The extracted nucleic acids were then precipitated by adjusting the salt concentration to 0.3 mol/L sodium acetate and adding 2.5 volumes of cold absolute alcohol. The nucleic acids were concentrated by centrifugation (11,000 rpm), washed twice with 70% ethanol, dried under vacuum, and resuspended in 1 ml of TE buffer [10 mM Tris hydrochloride (pH 7.5) and 1 mmol/L ethylenediaminetetraacetic acid]. The DNA concentration was estimated by monitoring the absorbance at 260 nm with a Beckman DU-7 spectrophotometer.

DNA was purified from nasopharyngeal aspirates and samples of artificially ruptured membranes by directly extracting these samples with an equal volume of phenol/chloroform/isoamyl alcohol. The DNA was then precipitated in ethanol and resuspended in TE buffer. The amount of DNA obtained from these samples was usually small and the entire sample was used in the hybridization analysis.

Hybridization analysis. DNA (10 to 15 μg) extracted from cervical samples and the total DNA extracted from artificially ruptured membranes and nasopharyngeal specimens was cleaved with the restriction endonuclease *Pst* I as recommended by the manufacturer (New England Biolabs). The resulting DNA fragments were fractionated by electrophoresis in a 0.8% agarose gel and then transferred to a nylon filter membrane (Amersham Hybond-N). DNA hybridization analysis was performed at −20° C with a modification of the Southern blot technique.[17] Molecular probes corresponding to HPV types 6, 11, 16, 18, 31, 33, and 35 were amplified and purified with standard laboratory methods. The HPV genomes were purified from flanking bacterial plasmid DNA and then radiolabeled with α ^{32}P-deoxycytidine triphosphate. Hybridization analysis of DNA extracted from exfoliated cervical cells was performed in triplicate. The molecular probes used in the three hybridization reactions were HPV-16/18, HPV-31/33/35, or HPV-6/11.

†Nasopharyngeal samples were all obtained with the DeLee suction device. Samples were obtained after spontaneous vaginal delivery or cesarean section.

Results

Samples of exfoliated cervical cells obtained from 45 pregnant women during their first- and third-trimester examinations were analyzed for the presence of HPV DNA. Comparison of the DNA hybridization results from cervical samples obtained during the patients' first- and third-trimester examinations revealed both a progression (in some patients) and a regression (in other patients) in the detectable levels of HPV DNA (see accompanying article, pp. 50-5). The total number of patients with results positive for HPV DNA in one or both of the cervical samples was 24/45 (55.5%). The cervical DNA samples were hybridized with three different groups of HPV molecular probes. The distribution of viral types found in the cervical samples is shown in Table I.

At the time of delivery, the neonatal nasopharyngeal aspirate was obtained for this study. Forty-one of the 45 aspirate samples were obtained from neonates after spontaneous vaginal delivery and four were obtained from infants who were delivered by cesarean section.

SVD, Spontaneous vaginal delivery.

*Mothers were considered to have positive results if either their first- or third-trimester sample of cervical cells was positive for HPV DNA.

The nucleic acids were extracted from these samples and assayed for the presence of HPV DNA (Fig. 1). The hybridization results have been compared with the hybridization results obtained from the respective mothers (Table II).

HPV DNA was detected in 15 of the 41 (36.5%) nasopharyngeal samples obtained from babies who were delivered vaginally. No viral DNA was detected in the four samples obtained from babies delivered by cesarean section. Four nasopharyngeal samples that were positive for HPV DNA were from babies whose mothers' first- and third-trimester examination results were negative for HPV DNA. One of these mothers had cytologically positive results for HPV (condylomatous atypia) during her first-trimester examination; two mothers' results were positive for HPV DNA in a sample of exfoliating cervical cells obtained during her first postpartum examination (see accompanying article pp. 50-5).

A sample of amniotic fluid from artificially ruptured membranes was obtained from 13 mothers. Total DNA was extracted from these samples and analyzed for the presence of HPV DNA (Table III). One sample of amniotic fluid was obtained from a patient undergoing elective cesarean section. The two samples from artificially ruptured membranes that were positive for HPV DNA were obtained from patients who also had positive results for HPV DNA in their cervical cells.

Comment

We have demonstrated the presence of HPV DNA in the oral cavity in 11 of the 23 (47.8%) children who were delivered vaginally from mothers who had detectable levels of HPV DNA in cervical cells. The presence of viral DNA does not in itself imply the presence of infectious virus, but it does demonstrate a mechanism by which the virus could be transmitted at the time of birth. The commercially available polyclonal antibody which recognizes papillomavirus capsid protein should be used, in complementary experiments, to detect HPV capsid protein in the nasopharyngeal aspirate. In addition, this study did not make use of a matched nonpregnant control group; such a control group should be part of any subsequent follow-up study.

It is difficult to explain the four nasopharyngeal aspirates that were positive for HPV DNA when maternal cervical cells were negative for HPV DNA. However, as noted, three of the four mothers had either cytologic evidence of HPV infection or detection of HPV DNA in cervical samples obtained post partum. The observed fluctuations of detectable HPV DNA in exfoliated cervical cells (see accompanying article pp. 50-5) may explain the last case, in which HPV DNA was detected in the neonate but not in the mother.

The two positive samples from artificially ruptured membranes could have resulted from contamination of the amniotic fluid by vaginal secretions during the sample collection. However, a recent report[18] described HPV DNA associated with foreskins obtained within 3 days of birth from infants who had routine circumcision. The authors of this report argue that the HPV DNA was the result of a viral infection instead of residual HPV DNA from the maternal vaginal secretions at the time of birth. This explanation would suggest that the HPV infection of the foreskin occurred in utero. The presence of HPV DNA in the amniotic fluid also suggests that transmission of the virus can occur in utero. The small number of NAROM samples and the probability of contamination of these samples with cervical or vaginal secretions prevent us from making a definitive interpretation of these data. To alleviate the problem of contamination of these samples, this part of the study should be repeated with amniotic fluid collected transabdominally.

A number of HPV types in addition to HPV-6 and HPV-11 have been found in oral lesions, including HPV-13,[1] HPV-16,[2,3] and HPV-32,[19] and in laryngeal carcinomas, HPV-30.[4] In our study, 12 of the 25 (48%) HPV DNA-positive cervical samples contained HPV types 16 or 18 in their cervical cells; nine of the 25 (36%) were of an undetermined HPV type. Therefore any HPV type that demonstrates a tissue specificity for oral and anogenital mucosa can be transmitted from mother to neonate at birth.

No cervical sample used in this study contained HPV-6 or HPV-11 DNA, and no attempt was made to determine the HPV types associated with the nasopharyngeal samples. No biopsies were performed on vaginal or vulvar epithelial tissue. If the population size was increased, and it included patients with exophytic condyloma of the vulva or vagina (which usually contain HPV types 6 or 11[7]), then the probabilty of detecting these viral types in the nasopharyngeal aspirate would increase. In juvenile oral lesions, HPV-6 and HPV-11

types are associated with juvenile-onset laryngeal papillomatosis, a rare but potentially dangerous disorder. The results from this study define a perinatal transmission of HPVs for the first time. Therefore children born to mothers with overt condyloma may warrant DNA hybridization analysis of their nasopharyngeal aspirates. The information obtained may help in subsequent detection and management of children with juvenile-onset laryngeal papillomatosis.

We thank J. Cohn (Department of Orthopedics, Pennsylvania Hospital) and K. Kushner (Department of Pathology, Pennsylvania Hospital) for expert help in data presentation. We also thank R. Unger (Hospital of the University of Pennsylvania, Department of Obstetrics and Gynecology) for critically reviewing this manuscript, and Microprobe Corp. of Bothell, Wash., for providing HPV-33 and HPV-35 molecular probes.

A ten-year experience treating cervical intraepithelial neoplasia with the CO_2 laser

Michael S. Baggish, MD, James H. Dorsey, MD, and Mark Adelson, MD
Syracuse, New York, and Baltimore, Maryland

Between 1977 and 1987, the CO_2 laser was used to treat 4024 women who were diagnosed by cytology studies, colposcopy, and biopsy examination to have cervical intraepithelial neoplasia. On the basis of specific indications, these women were treated by vaporization, excisional conization, or combination conization procedure. The evolution of methodology for each laser technique was based on specific pathophysiology and long-term observation of results. A total of 3070 patients underwent vaporization, 2881 of whom had no evidence of disease after one laser exposure (93.8%). Of the 954 patients who had laser excisional procedures, 925 (97%) had no evidence of disease. The most common complications observed were intraoperative and postoperative bleeding; however, sutures were required in only 1.34% of the latter. The risks of cervical stenosis (1.1%), incompetent cervix (0%), and pelvic infection (0.05%) were very low. This 10-year study demonstrated that the CO_2 laser was a highly effective method for treating cervical epithelial neoplasia and had the added benefit of preserving reproductive function and anatomic integrity. (Am J Obstet Gynecol 1989;161:60-8.)

Key words: Laser, CO_2 laser, cervical epithelial neoplasia, cervical neoplasia

The early diagnosis and subsequent treatment of preinvasive neoplasia of the cervix result in a greatly diminished risk of invasive disease and preservation of cervical function and anatomy. Numerous radical and conservative therapeutic techniques have been advocated during the past 30 years; however, in recent years the trend has been directed toward outpatient methodology associated with local or no anesthesia. Although tissue-conserving treatment programs have both advocates and detractors, the question of equivalent efficacy remains a point of controversial contention. Townsend et al.[1] showed that inaccurate pretreatment assessment invariably leads to faulty diagnosis, improper selection of therapy, and subsequent discovery of invasive carcinoma.

The evolution of conservative therapy began in the 1950s and 1960s with sharp conization, continued with cryosurgery during the late 1960s and throughout the 1970s, and culminated with the advent of CO_2 laser surgery in the past decade. Initially, the laser appeared to have little advantage over less complex, albeit less precise, methodology. However, as time passed and experience with the new modality was gained, therapeutic results sharply improved.

The purpose of this article is to provide data based on one of the largest case series ever assembled that used the CO_2 laser as the singular therapeutic entity and present follow-up results over a 10-year time period.

From the State University of New York Health Sciences Center, Syracuse, Crouse-Irving Memorial Hospital, and Greater Baltimore Medical Center.

Material and methods

Between 1977 and 1987, 3070 women underwent CO_2 laser vaporization and were followed-up for a minimum of 1 year. Every woman had a confirmed histopathologic diagnosis of cervical intraepithelial neoplasia ranging in grade from 1 to 3; 954 patients similarly diagnosed with cervical epithelial neoplasia 1 to 3 had laser excisional or combination conization from 1979 to 1987. The minimum follow-up period was 1 year (321 patients); 1104 women were followed by ≥1 to 5 years and 2599 patients were followed ≥5 to 10 years. All laser procedures were carried out at one of four hospitals: Crouse-Irving Memorial Hospital, Syracuse, N.Y.; Greater Baltimore Medical Center, Baltimore, Md.; Mount Sinai Hospital, Hartford, Conn.; State University of New York Health Science Center—University Hospital, Syracuse, N.Y. Of the 4024 patients, 3098 were white, 845 were black, and 81 were Hispanic or Oriental. Patient ages ranged from 14 to 81 years (mean age, 26.2 years).

Patients were referred either from colposcopy clinics, private offices, or general gynecology clinics because of abnormal cytologic studies or less commonly after a biopsy diagnosis of cervical epithelial neoplasia. Every patient underwent a repeat colposcopic examination and one or more colposcopically directed biopsies. The endocervical canal was investigated by either blind endocervical curettage or endoscopic examination of the

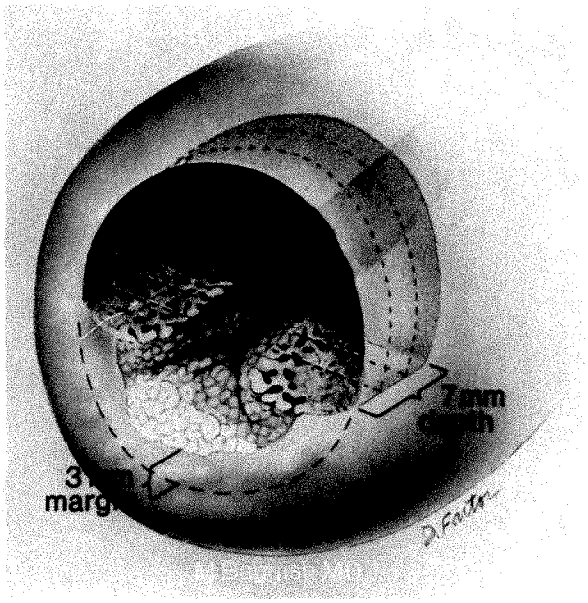

Fig. 1. Three-dimensional view of cervix reveals an abnormal transformation zone (white epithelium and mosaic) at 6-o'clock position. Laser vaporization is performed by cleaving plane on plane of tissue until a depth of 7 mm is reached. Note projection of endocervical clefts after the upper one half of the cervix has been vaporized. The 3 mm margin is designed to take into account possible penetration of neoplasia into the underlying crypts. Projection of the endocervical canal toward the internal os is seen as the shaded area.

canal followed by directed endocervical biopsy. The latter procedure was carried out by means of a small endoscope that was inserted into the cervical canal after swabbing or irrigating the mucosa with 4% acetic acid. Lesions were schematically mapped, and the geographic extent was sketched, with specific notation made of any endocervical or vaginal extension.

Additionally cultures were obtained for the determination of gonorrhea and *Chlamydia* beginning in 1983. Women with positive cultures were treated with a 2 gm injection of spectinomycin or 500 mg of tetracycline (or equivalent) orally administered four times per day for 10 days, respectively.

Forty percent of laser vaporizations were performed in the office, whereas 1873 patients (60%) underwent surgery in the outpatient operation room. Fifty laser conizations have now been done in the office under local anesthesia; the remainder were performed in the outpatient operating room.

Patients undergoing laser vaporization in the office received ibuprofen (Motrin), 400 to 600 mg, 30 minutes before vaporizaton. All patients received suitable informed consent and were previously given an informational booklet describing the details of laser treatment and postoperative routines.

In this series 1520 patients had no anesthesia for vaporization, 1111 patients had local anesthesia, and

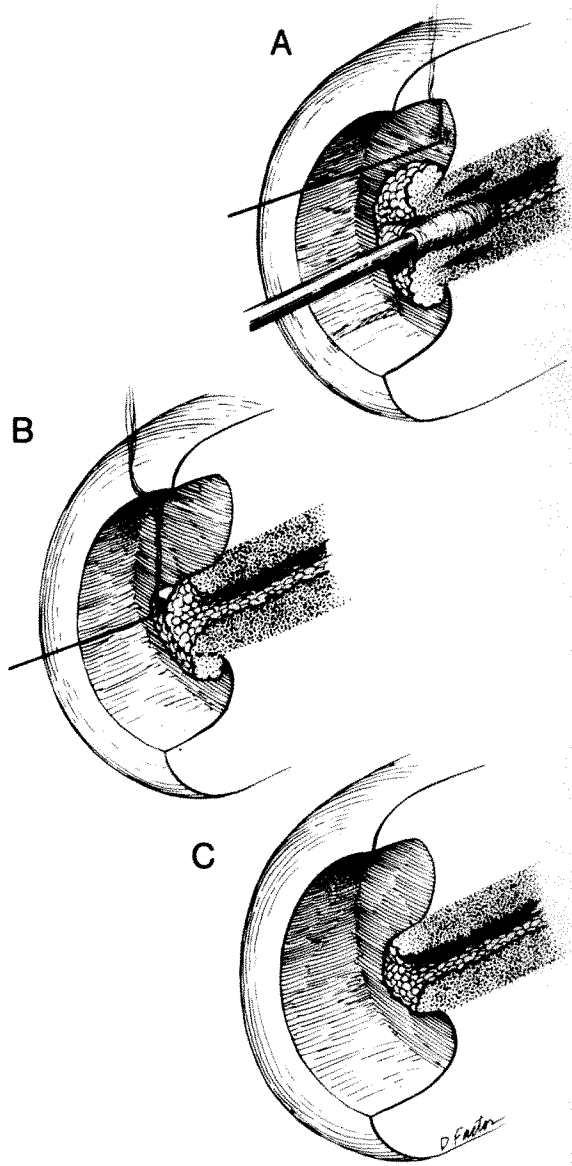

Fig. 2. Cervical vaporization is finished off by setting the location of the new external os. This is accomplished by vaporizing a 2 mm trench just peripheral to the endocervical margin and is facilitated by placing a moistened cotton-tipped applicator into the canal *(A)*. Next, the everted mucosa is vaporized away (clipping) *(B)*, resulting in ablation of addition 2 to 3 mm of tissue *(C)*.

439 patients had general anesthesia. For laser excisional conization 304 patients had local anesthesia and 650 underwent general anesthesia.

Several types of CO_2 laser equipment were used during the years patients were treated, including (1) Coherent 400, (2) Cavitron A0300, (3) Cooper Lasersonics 500Z, (4) Sharplan 733 and 1100, (5) Xanar XA50, and (6) Minnesota laser, Portalase 200. Current laser equipment used for the treatment of cervical intraepithelial neoplasia has a variable spot feature incorporated in the construction of the micromanipulator, a microscope

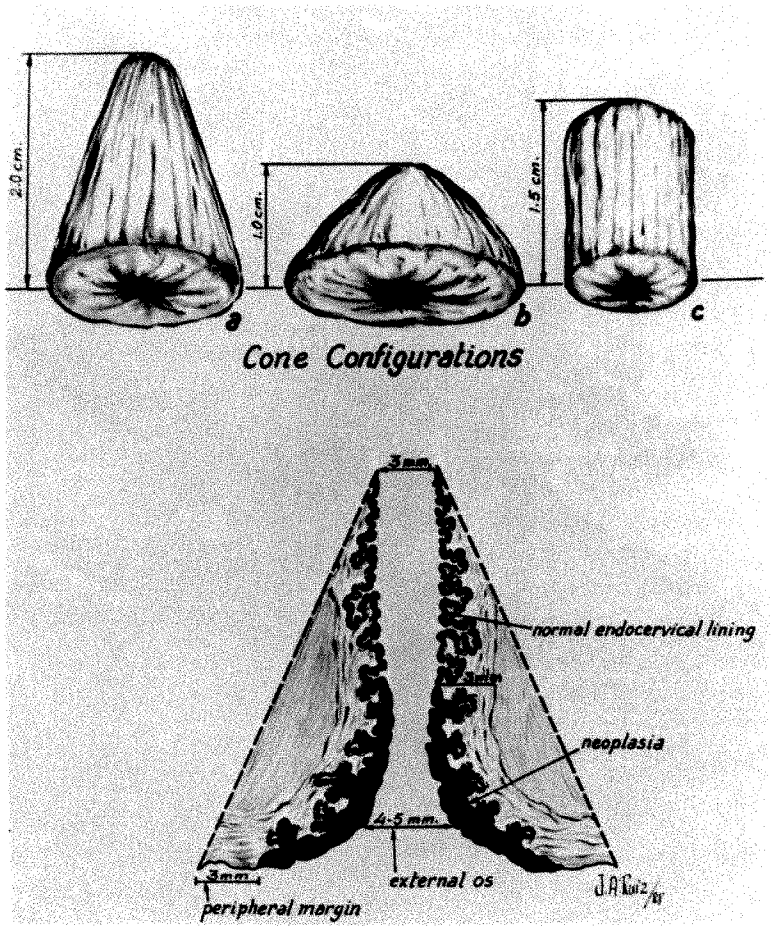

Fig. 3. Geometry of excisional cervical specimens depends on characteristics of geography of neoplasia. *a*, Most common configuration of a laser excisional cone. Base measures about 1.5 to 2 cm and height measures 2 cm. *b*, Broad-based cone measuring 2 to 2.3 cm with a height of approximately 1 to 1.2 cm. *c*, Narrow cylinder made in conjunction with peripheral vaporization (laser combination cone) measures about 1 by 1.5 cm.

Table I. Criteria for performance of laser vaporization and conization

Laser vaporization (all must be satisfied)	*Laser conization (any one)*
Lesion must be ectocervical in location	Lesion extends into endocervical canal
Lesion must be proved by biopsy examination to be intraepithelial	Directed biopsy specimen suggests possible stromal invasion
Endocervical canal must be established to be free of disease by negative endocervical curettage or negative endoscopic examination of canal	Endocervical sampling reveals neoplastic tissue within canal
	Papanicolau smear/biopsy disparity exists*

*A thorough vaginal colposcopic examination has been performed.

with multiple magnification settings, and superpulse capability. Although several micromanipulators permit spot (beam diameter) reduction to 0.2 to 0.3 mm at 10 to 20 W, practically minimum spots delivered at 30 to 40 W of power ranged from 0.4 to 0.5 mm diameter. First-generation lasers produced fixed spots of 1.5 to 2.0 mm diameter. Power capabilities ranged from 1 to 100 W.

Technique for vaporization. Table I lists the criteria for laser vaporization. With a power density of approximately 500 to 800 W/cm^2 (20 W with 1.5 to 2 mm spot), a 3 mm margin was traced along the peripheral extent of the abnormal transformation zone. Laser power was turned up to 30 to 60 W depending on the equipment used, and vaporization was carried out in 1 to 2 mm planes that used a small circular technique by

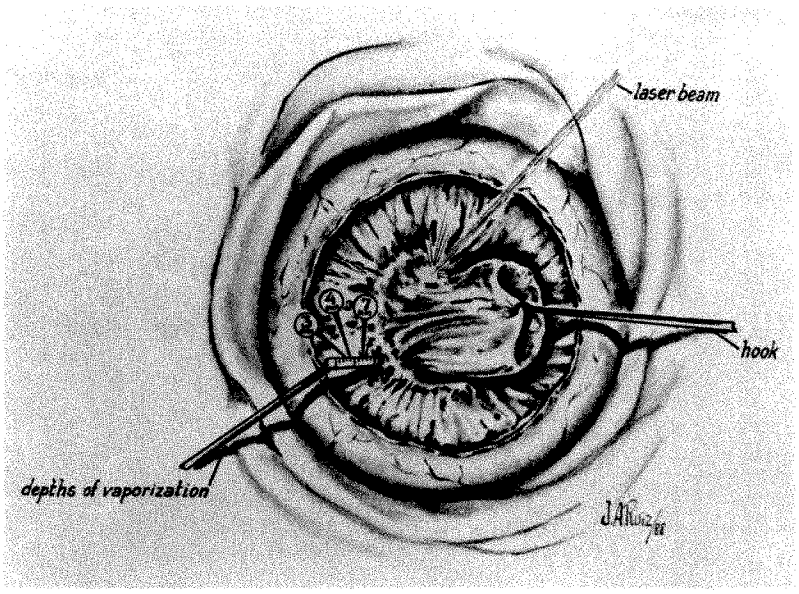

Fig. 4. Easiest method for performing a combination cone is to first vaporize peripheral extent of biopsy that established intraepithelial neoplasia. Next, central core of cervix is excised to a depth of approximately 1.5 to 2.0 cm. Since half the surrounding tissue (7 mm) has already been vaporized, excisional part of operation may be quickly completed.

manipulating the joy stick in a clockwise or counterclockwise motion. Planes were cleaved until a central depth of 7 mm was reached (Fig. 1). Depth was measured by use of a measuring rod device and by relating to the surrounding surface epithelium of the cervix. Char material was swabbed out of the crater by means of large cotton swabs soaked with 4% acetic acid. Next, a small cotton-tipped applicator was inserted into the endocervical canal. Laser power was reduced to 15 to 20 W, and the laser spot was decreased to approximately 1 to 1.5 mm spot diameter. The collagenous stroma in juxtaposition to the endocervix was shallowly vaporized, causing the endocervical mucosa to evert (buttoning); next, 2 to 3 mm more of the endocervix was narrowly vaporized (clipping) (Fig. 2). Thus the margin of endocervix could be placed wherever the operator desired; generally the squamocolumnar junction was located just inside the anatomic external os. The net result was a vaporization cone approximately 9 mm in depth that was narrower at the apex and widest at the ectocervical margin.

Technique for excisonal conization. Cones were always performed by means of the microscope and micromanipulator. The geometric shape of the excision cone specimen was governed by the extent of the abnormal transformation zone. Table I lists the expanded criteria for performing excisional conizations. A thorough colposcopic examination was performed before conization. After the abnormal transformation zone was identified, utilizing power densities of 800 W/cm^2, 1 to 1.5 mm trace spots were placed into the cervix with no anesthesia, allowing a 3 mm margin peripheral to the abnormal tissue. Next, a 1:30 vasopressin local anesthetic (1% lidocaine) mixture was injected directly and shallowly into the substance of the cervix under pressure. No stay sutures whatsoever were placed into the cervix. Fig. 3 shows several cone configurations used during this study. With the help of a specially designed 10-inch titanium laser hook, the tissue was manipulated to achieve the appropriate sculpted effect.

Power was turned up to 30 to 60 W if available on the laser equipment; however, cones could be performed effectively at 20 W. Spots were adjusted to 0.3 to 0.5 mm. An incision was made by moving the micromanipulator slowly connecting the trace spots. This initial incision usually penetrated 5 to 7 mm into the depths of the cervical connective tissue. The endocervical margin was cut off with a sharp scalpel or a superpulsed laser beam.

Technique for combination conization. When cervical intraepithelial neoplasia extended far out onto the portio involving three to four quadrants or spread onto the vaginal mucosa and also involved the endocervical canal, a narrow excisional cone, that is, 1 cm in diameter, was combined with ectocervical vaporization.

Method 1. The ectocervical (vaporization) margin and cone margin were traced with laser impact spots. Power was adjusted to 20 to 60 W, depending on the equipment; the spot increased to 2 mm diameter and vaporization was carried to a depth of 7 mm, banking off to 4 mm on the farther periphery of the ectocervix, then to just under 1 mm as the vagina was approached.

The laser hook was placed into the margin of the

‡One patient had prior conization and was lost to follow-up for 3 years; three patients had diagnosis of invasion at time of conization.

cervical remnant to be excised, usually beginning at the 12-o'clock position. Essentially 7 mm of the 1.5 cm portion of the central remanant of the cervix had already been removed (Fig. 4). A small excisional conization was carried out. The coned specimen measured approximately 1 by 1.5 cm. Obviously, the ectocervical margin of this narrow cone will always show cervical epithelial neoplasia.

Method 2. The two series of trace spots were placed into the cervix as described in method 1. In this instance the laser excisional conization was performed by first removing the 1 by 1.5 cm cylindric specimen. Next, the peripheral vaporization was carried out. The operative site was finished off in the same way as previously described (method 1).

Results

Vaporization. Of the 3070 women who underwent a single laser vaporization, 2881 (94%) showed no evidence of disease after at least a 1-year follow-up period. Interestingly, the best results were obtained in the 1281 women diagnosed with grade 3 cervical intraepithelial neoplasia (no evidence of disease, 96%). Table II provides details of these treatment results by grade of disease. Persistence was seen in all grades of cervical intraepithelial neoplasia and totaled 133 women (4.3%); 127 of the 133 patients (95%) with persistent disease had condylomatous disease with or without atypia; only six cases of true cervical epithelial neoplasia were diagnosed. Recurrence was observed almost exclusively in the grade 1 cervical intraepithelial neoplasia group and always took the form of flat condyloma. Progression was identified in only two patients (0.065%).

Excisional conization. Seventy-three women who underwent laser excisional conization had disease that extended to the margin or had an indeterminate margin, and 881 (93.4%) had negative margins (Tables III and IV). Four cases of invasive carcinoma, one case of microinvasive epidermoid, two cases of epidermoid, and one case of adenocarcinoma were diagnosed after section and pathologic evaluation of the cone specimen. The one case of epidermoid carcinoma was diagnosed in a patient who had positive margins (initial diagnosis was grade 3 cervical intraepithelial neoplasia with positive endocervical margin) and did not return for follow-up examination for 3 years. She subsequently appeared at a neighboring clinic because of vaginal bleeding and was referred back to the colposcopy clinic where a directed biopsy specimen showed invasive epidermoid carcinoma. Clinical staging of these invasive cases revealed the last case to be stage IIA; the remaining two epidermoid carcinomas were stages IA and IB; the adenocarcinoma was a very superficially invasive ("microinvasive") lesion with no vascular involvement. Follow-up of the remaining 69 cases with positive margins revealed that 44 had no evidence of disease 3 to 7 years after the initial operation. Twenty-five women had persistent or recurrent abnormal cytologic studies, which prompted subsequent biopsy and repetitive therapy. Thirteen women had repeat conization: four showed no disease on the sectioned specimen, three showed condylomatous atypia; one showed grade 2 cervical intraepithelial neoplasia; and five showed grade 3 cervical intraepithelial neoplasia. One cone again showed indistinct margins, and the patient continues to be followed carefully by colposcopy and

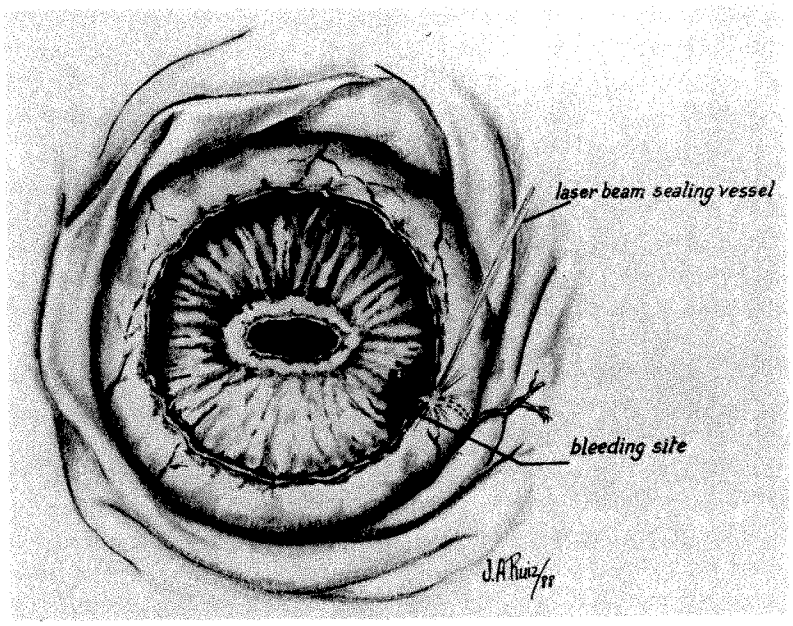

Fig. 5. When intraoperative bleeding occurs during laser surgery of the cervix, the easiest manner of dealing with the problem is to coagulate the vessel before it reaches the crater. The laser beam is aimed peripherally from the bleeding site, laser spot is enlarged (power density reduced), and coagulation of the traversing vessel is accomplished.

cytologic studies. The 12 women who had hysterectomy showed residual cervical intraepithelial neoplasia: grade 1, one case; grade 2, one case; grade 3, eight cases; and no disease in two cases (Table IV).

In the final analysis, 954 women fulfilled the criteria for laser excisional conization, and 925 (97%) had no evidence of persistent or recurrent disease during follow-up examination of up to 8 years' duration (Table V).

Complications. Bleeding was the most common complication observed during vaporization and excisional procedures. The most frequent sites for intraoperative bleeding during vaporization were the two posterior quadrants of the cervix and was most frequently observed in cervices showing histologic evidence of acute cervicitis and neoplasia. Light bleeding was easily controlled by defocusing the laser beam to a >2 mm spot, thus coagulating the vessel peripheral to the crater and sealing it off before its entrance into the crater (Fig. 5). Arterial pumping hemorrhage was more commonly (3.5%) associated with laser conization procedures but also was seen during vaporization (3%). Suturing the vessel under colposcopic guidance with 3-0 Vicryl in a figure-of-eight fashion proved to be the simplest and most direct approach.

Delayed bleeding was most frequently observed after laser vaporization. This problem was usually self-limited and occurred 4 to 10 days after vaporization. In 170 cases this bleeding persisted more than 48 hours (vaporization group). Of the 170 cases, 142 were controlled by the application of Monsel's solution to the bleeding vessel. In 38 cases the placement of one or two sutures was required. Twenty-five patients continued to have light bleeding for 3 to 4 weeks. In this subset healing occurred without interruption, and the bleeding eventually stopped spontaneously.

Table IV. Seventy-three cases of laser conization with positive margins

Invasive disease	4
No further treatment	44
Repeat conization	13
Hysterectomy	12

Postexcisional conization bleeding was seen less frequently than after vaporization. In 31 cases bleeding continued unabated after 7 to 10 days. In 16 cases sutures were required; 15 cases responded to laser coagulation or the application of Monsel's solution. Comparing significant delayed laser bleeding by methodology, the relative risk after vaporization was 1.7 times greater than that after conization.

Two cases of pelvic infection were observed in the entire series. One woman was observed to have a fever of 102° F 48 hours after laser combination cone. On examination she had a purulent cervical discharge and abdominal pain, together with direct and rebound tenderness. The patient was admitted and treated with intravenous antibiotics and discharged home within 4 days after admission. The second patient developed a

general febrile reaction within 2 hours of the laser vaporization. A temperature of 101.8° F was associated with shaking chills. The patient was admitted and treated with intravenous antibiotics. By 8:00 PM on the evening of surgery, she was afebrile. Blood cultures subsequently revealed β-hemolytic streptococcus. She was sent home after 24 hours on oral antibiotics.

Pain was not a significant factor after surgery.

A pink or watery blood-tinged discharge peaked at 72 to 96 hours after laser vaporization. The discharge gradually diminished over the next 7 days and disappeared. Blood-tinged discharge lasted as long as 2 weeks after laser excisional procedures. A small number of patients (≤0.5%) had discharge persisting beyond 3 weeks.

No case of an incompetent cervix was seen.

Cervical stenosis, which was defined as scarring and narrowing of the endocervical canal such that the opening of the canal measured <2 mm in diameter, was observed in 15 cases after the combination conization. In addition, 24 cases were seen after simple excisional conization. Stenosis after vaporization was uncommon and was noted in only six cases.

Comment

The treatment of cervical disease was one of the earliest applications of laser technology in gynecology. Between 1977 and 1987 numerous articles were published in the peer-review literature citing experience with the CO_2 laser as a method for eradicating cervical intraepithelial neoplasia.[2-9] Early treatment programs attempted to focally treat cervical intraepithelial neoplasia, penetrated to depths of only 2 to 3 mm, failed to consider peripheral margins, vaporized disease in the endocervical canal, and used low-power densities. On the basis of the early work of Jordan and Mylotte,[10] Baggish,[11] Masterson et al.,[12] Bellina et al.,[13] and Anderson,[14] the entire transformation zone was first vaporized to a depth of 5 mm and then later to 7 mm. A peripheral margin of 3 mm was established to take into account the deep penetration of neoplastic cells into the endocervical crypts to a depth of 2.92 mm (95% of cases samples).[15] Burke[16] substantively demonstrated that the treatment results improved when endocervical extension of cervical epithelial neoplasia was excluded from treatment by vaporization.

The data presented here represent the pinnacle of 10 years of evolution and the development of CO_2 laser vaporization into a fine art. Few conservative techniques can match the results of laser ablation of cervical epithelial neoplasia, considering that the disease can be treated in the office, the method requires no anesthesia or only local anesthetic injection, and no selection is made for grade of cervical intraepithelial neoplasia or extent of geographic spread. The final product of this precise technique is, in fact, equivalent to a shallow conization procedure.

The buttoning (eversion of endocervical margin) technique was performed between 1979 and 1983 and was originally conceived because of the fear of cervical stenosis. As cases were followed over the years, the risk of stenosis proved to be small; however, many women developed prolapse of the endocervical mucosa.[17] This endocervical protrusion resulted in vaginal discharge and contact bleeding. Since 1983 the everted endocervical mucosa was clipped, that is, precisely vaporized to a further depth of approximately 3 mm. The end result was the creation of a conical crater approaching 1 cm in depth with the subsequent squamocolumnar junction located at the anatomic external os.

Using high-power densities, that is, 1000 W/cm^2, resulted in reduced thermal injury, predictable healing, and rapid attainment of appropriate crater depth.[6] The last item is important because as cellular injury occurs as a result of the thermal action of the laser, water rapidly diffuses into injured tissue and produces swelling. Therefore slow laser vaporization with low-power densities results in the crater "filling in" before completion of treatment. In actuality more tissue is lost and greater peripheral heat damage results if the appropriate specifications are not followed. Compared with other conservative treatment techniques, the laser offers many advantages. Cryosurgery cannot be properly tailored to the geographic extent of the neoplastic lesion. The therapeutic results of this methodology also falter when grade 3 cervical intraepithelial neoplasia is treated. In addition, when one finishes, a cryosurgical procedure, the depth of treatment, and the peripheral margins are inexact. The technique of radical electrocoagulation of cervical intraepithelial neoplasia with needle-and-ball cautery yields results similar to those of the laser but requires general anesthesia, can precipitate a high volume of blood loss, and is clearly the antithesis of controlled, precise, limited tissue trauma. The cold coagulator is less expensive, more effective, and less traumatic than the radical electrocautery; however, to date a small number of cases has been reported at a limited number of centers.

Pesky intraoperative bleeding occurred in approximately 8% to 10% of cases, especially early in the series. The ability to rapidly defocus the laser beam by using the variable spot feature controlled this problem rapidly and effectively. In addition, the technique of coagulating the offending vessel peripherally, that is, before it enters the crater, has proved to be the very best method for controlling this problem.

The presence of chlamydial cervicitis by culture or serologic studies or biopsy evidence of acute cervicitis premonitored an increased chance of immediate and delayed bleeding. Pretreatment of these infections with

tetracycline or other appropriate antimicrobials reduced the risk of bleeding by 50%. The risk of infection after laser surgery of the cervix was predictably small, that is, 0.05%. Theoretically the heat of vaporization is 100° C, and temperatures of 800° C have been measured when incandescence is produced (burning off carbon). Survival of bacteria and viruses is doubtful when exposed to such high temperatures.

The efficacy of CO_2 laser elimination of cervical epithelial neoplasia was documented by the absence of disease in 94% of women who underwent vaporization. Those patients who had persistent or recurrent disease were almost universally (95%) diagnosed to have condylomatous disease of the cervix rather than intraepithelial neoplasia. This finding was not surprising, since one would hardly expect long-established sexual habits to rapidly change. Likewise, the skewed numbers of local recurrence and persistence in the grade 1 cervical intraepithelial neoplasia subset may possibly hinge on the basis that most of these cases were actually condylomatous disease initially. In addition, the human papillomavirus was likely to be present in cells within the endocervical canal above the area of treatment and in the surrounding vagina.[18] The diminished number of persistent and recurrent cases observed in the grade 3 cervical intraepithelial neoplasia group may be explained on the basis that this grade of disease is usually more extensive geographically and the laser surgery more radical and expansive.

For many years the specifications for laser vaporization were erroneously based, that is, the 7 mm depth, toward the goal of ablating the possibly involved endocervical glands. This hypothesis was, of course, inaccurate, since the depth of vaporization was actually determined by trial and error rather than by a preconceived plan. The logic behind sufficient depth of treatment more accurately related to the "gold standard" of conization and the fact that the proximal 1 cm of the canal contained the most likely cell population at risk for progression of cervical epithelial neoplasia.[19] Clearly, the best treatment results in all studies of conservative therapy for cervical epithelial neoplasia were witnessed in women undergoing excision cones. The only difference between this procedure and laser vaporization was the depth to which tissue was removed. Vaporization produced a defect not dissimilar to a small cone. The possible neoplastic involvement of the endocervical clefts was accounted for in the wide peripheral margin. Since the extension of these clefts onto the portio eventuated in a greater peripheral incursion into the stroma than was seen in those clefts emanating from the canal proper, the 3 mm margin of vaporization was more than adequate to provide for their elimination.

It follows that the routine performance of large cylinder–shaped cones to treat intraepithelial neoplasia makes little sense because nothing is accrued toward greater cure rates (Fig. 6); rather, a larger volume of stroma is sacrificed for no useful purpose.

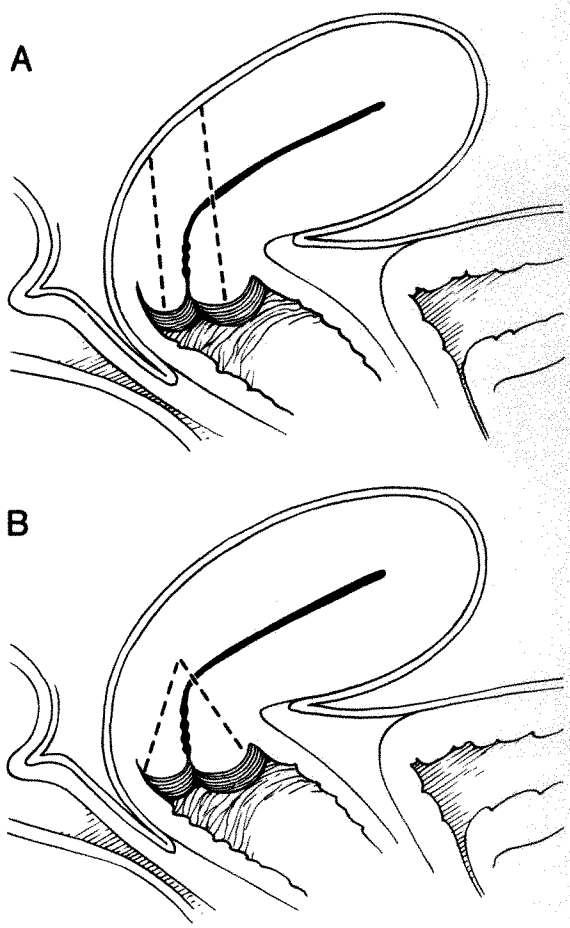

Fig. 6. Larger cylindric cervical excisions performed with a tightly focused laser beam may present a hazard of penetration into abdominal cavity, especially in acutely retroflexed or anteflexed uterus *(A)*. This complication may be avoided by sculpting the specimen in a conical or semi-conical shape *(B)*.

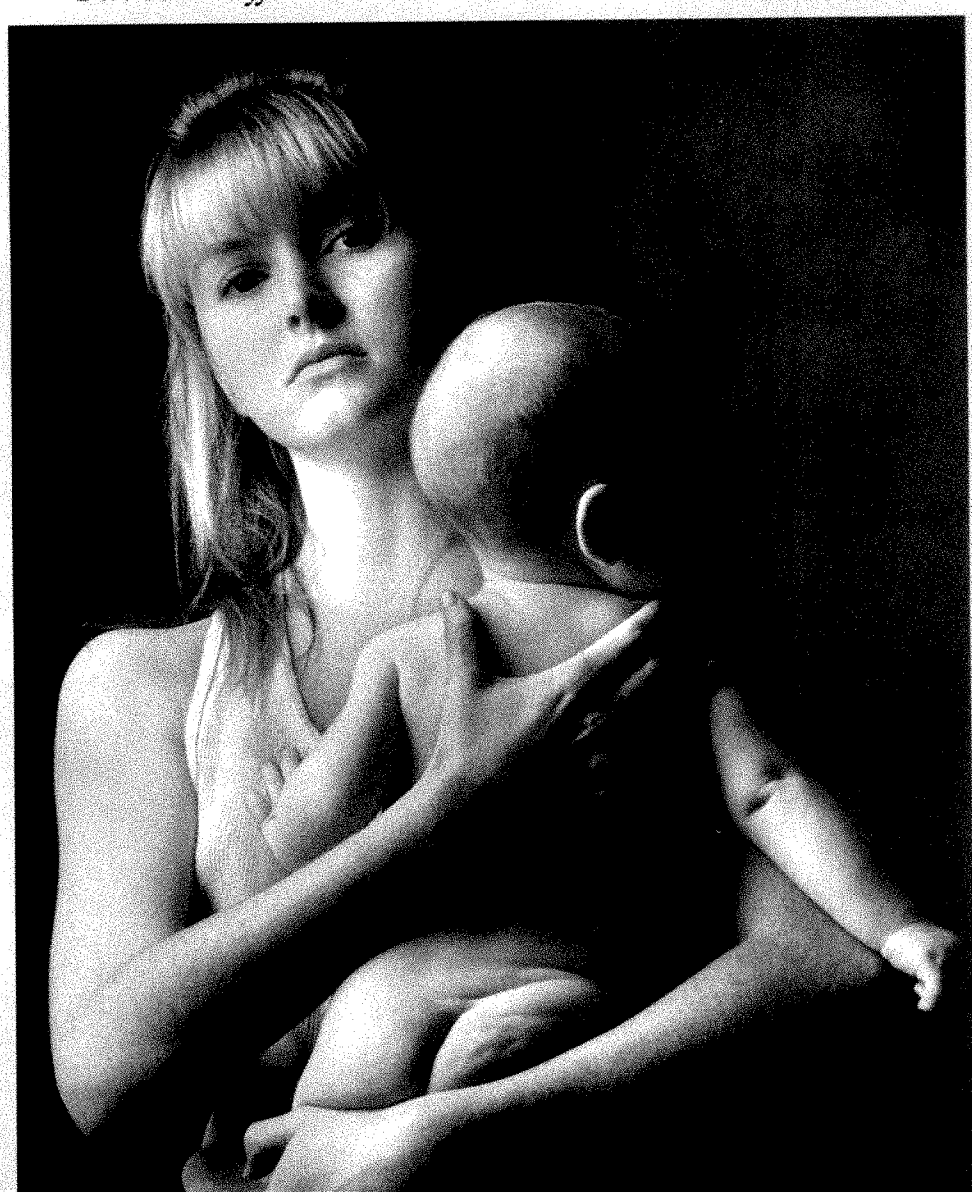
In a previous publication the risk of complications between laser vaporization and laser excisional conization was compared.[20] That study demonstrated very little difference between the two procedures other than the excisional procedure required a few minutes longer to complete. Both operations were done safely in the office under local anesthesia. The mean blood loss for both excisional cone and vaporization was equal. The major weakness of the vaporization technique was that the operation did not produce a specimen for the pathologist, whereas the excisional procedure provided a very ample sample of tissue.

In conclusion, CO_2 laser techniques for vaporizing cervical intraepithelial neoplasia are relatively easy to master; however, the finer points of microsurgical laser finishing and excisional procedures are skill related.



The abilities to appropriately adjust spot size, power density, and vary mode require experience. The final results of laser surgery as mirrored in this report clearly relate to the aforementioned. Individual surgeons must adjust power and more important power density relative to their ability to safely control beam velocity. Overall control must predominate over all other laser delivery parameters.

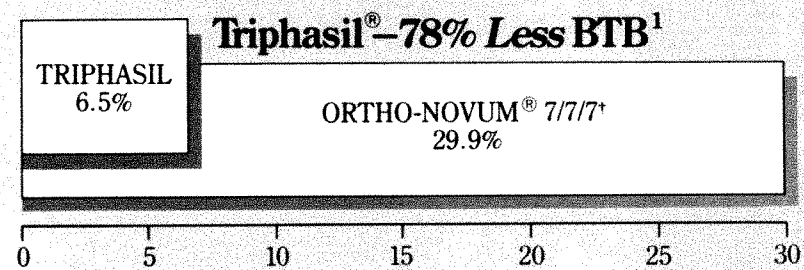
Fear from breakthrough bleeding can interrupt OC use.

"I was scared...
I didn't know what to do...
So I just said forget it ...
*I'm better off without it..."**



*Direct quote from OC user, data on file.

While the other triphasics have been minimizing the issue of breakthrough bleeding…

Wyeth has been minimizing breakthrough bleeding.*

In Cycle 1...the most critical cycle for compliance

In a separate study of over 4,300 women,[2] in over 70,000 cycles with TRIPHASIL, the total incidence of BTB was only 4.5%

TRIPHASIL –the only OC that needs no backup contraception††...from day 1

Triphasil®

Levonorgestrel and ethinyl estradiol tablets–Triphasic regimen
21- and 28-day regimens

MINIMIZES BTB... FROM DAY 1

* Serious as well as minor adverse reactions have been reported following the use of all oral contraceptives. See prescribing information.

† Norethindrone/ethinyl estradiol triphasic regimen, Ortho Pharmaceutical Corporation.

†† When used as directed.

1. Schilling LH, Bolding OT, Chenault CB, et al: *Am J Obstet Gynecol*, to be published. (Results of a randomized, four-cycle, multicenter U.S. comparison in 313 subjects: Triphasil® vs norethindrone triphasic OCs).

See brief summary of prescribing information on adjacent page.

© 1989, Wyeth-Ayerst Laboratories.

IN BRIEF:
TRIPHASIL®—6 brown tablets containing 0.050 mg levonorgestrel with 0.030 mg ethinyl estradiol; 5 white tablets containing 0.075 mg levonorgestrel with 0.040 mg ethinyl estradiol; 10 light-yellow tablets containing 0.125 mg levonorgestrel with 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day regimen)—Triphasic regimen.

Indications and Usage—TRIPHASIL® is indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OC's) as a method of contraception.

Contraindications—OC's should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during use of OC's or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

. *Thromboembolic Disorders and Other Vascular Problems*—An increased risk of thromboembolic and thrombotic isease associated with use of OC's is well established. Three principal studies in Great Britain and 3 in the U.S. ave demonstrated increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and hrombotic. These studies estimate that users of OC's are 4 to 11 times more likely than nonusers to develop these iseases without evident cause.

EREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with nd without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users ian nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

IYOCARDIAL INFARCTION (MI)—An increased risk of MI associated with the use of OC's has been reported, onfirming a previously suspected association. These studies, conducted in the UK, found, as expected, that the reater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hyper-holesterolemia, obesity, diabetes, history of pre-eclamptic toxemia) the higher the risk of developing MI, regardless f whether the patient was an OC user or not. OC's, however, were found to be a clear additional risk factor. In terms f relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing ondition to MI) are about twice as likely to have a fatal MI as nonusers who do not smoke. OC users who are also mokers have about a 5-fold increased risk of fatal MI compared to users who do not smoke, but about a 10- to 12-old increased risk compared to nonusers who do not smoke. Furthermore, amount of smoking is also an important ictor. In determining importance of these relative risks, however, baseline rates for various age groups must be iven serious consideration. Importance of other predisposing conditions mentioned above in determining relative nd absolute risks has not as yet been quantified; quite likely the same synergistic action exists, but perhaps to a sser extent.

ISK OF DOSE—In an analysis of data derived from several national adverse-reaction reporting systems, British vestigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to dose f estrogen in OC's. Preparations containing 100 mcg or more of estrogen were associated with higher risk of romboembolism than those containing 50-80 mcg. Their analysis did suggest, however, that quantity of estrogen ay not be the sole factor involved. This finding has been confirmed in the U.S.

STIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the K estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and onusers of OC's according to age, smoking habits, and duration of use. Overall excess death rate annually from rculatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/ 0,000; ages 45-49—140/100,000) risk being concentrated in older women, in those with long duration of use d in cigarette smokers. It was not possible, however, to examine interrelationships of age, smoking, and duration use, nor to compare effects of continuous vs. intermittent use. Although the study showed a 10-fold increase death due to circulatory diseases in users for 5 or more years, all these deaths occurred in women 35 or older. ntil larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to sess magnitude of relative risk for this younger group. Available data from a variety of sources have been ana-zed to estimate risk of death associated with various methods of contraception. Estimates of risk of death for each ethod include combined risk of contraceptive method (e.g., thromboembolic and thrombotic disease in the case of C's) plus risk attributable to pregnancy or abortion in event of method failure. This latter risk varies with effective-ss of method. The study concluded that mortality associated with all methods of birth control is low and below at associated with childbirth, with the exception of OC's in women over 40 who smoke. Lowest mortality is sociated with condom or diaphragm backed up by early abortion. Risk of thromboembolic and thrombotic disease sociated with OC's increases with age after about 30 and, for MI, is further increased by hypertension, hypercho-sterolemia, obesity, diabetes, or history of pre-eclamptic toxemia, and especially cigarette smoking. Physician and tient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebi-s, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric rombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A 4- to 6-ld increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OC's ould be discontinued at least 4 weeks before surgery of a type associated with increased risk of thromboembolism prolonged immobilization.

ERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Britain involving cerebro-scular disease and another in the U.S. concerning MI suggest an increased risk of these conditions in users of C's persists after discontinuation of the OC's. In the British study, risk of cerebrovascular disease remained vated in former OC users for at least 6 years after discontinuation. In the U.S. study, increased risk of MI rsisted for at least 9 years in women 40 to 49 years old who had used OC's for 5 or more years. Findings in th studies require confirmation since they are inconsistent with other published information.

Ocular Lesions—There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis sociated with use of OC's. Discontinue OC's if there is unexplained, sudden or gradual, partial or complete loss of sion; onset of proptosis or diplopia; papilledema; or retinal-vascular lesions, and institute appropriate diagnostic d therapeutic measures.

Carcinoma—Long-term continuous administration of either natural or synthetic estrogen in certain animal species creases frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none rrently contained in OC's, have been noted to increase incidence of mammary nodules, benign and malignant, in gs. In humans, 3 case-control studies have reported an increased risk of endometrial carcinoma associated with olonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases bmitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OC's. cases found in women without predisposing risk factors (e.g., irregular bleeding at the time OC's were first given, lycystic ovaries), nearly all occurred in women who had used a sequential OC. These are no longer marketed. No dence has been reported suggesting increased risk of endometrial cancer in users of conventional combination or gestogen-only OC's. Several studies have found no increase in breast cancer in women taking OC's or estrogens. e study, however, while also noting no overall increased risk of breast cancer in women on OC's, found an excess k in subgroups of OC users with documented benign breast disease. Reduced occurrence of benign breast tumors users of OC's has been well documented. In summary, there is at present no confirmed evidence from human idies of increased risk of cancer associated with OC's. Close clinical surveillance of all women on OC's is, never-ldess, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate gnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or h breast nodules, fibrocystic disease, or abnormal mammograms should be monitored with particular care if they ct to use OC's.

Hepatic Tumors—Benign hepatic adenomas have been found to be associated with use of OC's. One study owed that OC's with high hormonal potency were associated with higher risk than lower potency OC's. Although ign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been orted in short-term as well as long-term users. Two studies relate risk with duration of use of OC's, the risk ng much greater after 4 or more years' use. While hepatic adenoma is rare, it should be considered in women senting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma e been reported in women on OC's. Relationship of these drugs to this type of malignancy is not known.

Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring—e of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously nage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, e increased risk of developing in later life a form of vaginal or cervical cancer ordinarily extremely rare. This risk been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence now that OC's ther enhance risk of developing this type of malignancy, such patients should be monitored with particular care if y elect to use OC's. Furthermore, 30 to 90% of such exposed women have been found to have epithelial changes he vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is recursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. ough similar data are not available with use of other estrogens, it cannot be presumed they would not induce ilar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been orted with use of sex hormones, including OC's, in pregnancy. One case-control study estimated a 4.7-fold ease in risk of limb-reduction defects in infants exposed in utero to sex hormones (OC's, hormonal withdrawal s for pregnancy, or attempted treatment for threatened abortion). Some exposures involved only a few days. a suggest that risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual rtion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OC's. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OC's is unknown. It is recommended that, for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing OC's. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at time of first missed period, and further use of OC's should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and advisability of continuation of the pregnancy should be discussed. It is also recommended that women who discontinue OC's with intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this. The administration of progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease*—Studies report increased risk of surgically confirmed gallbladder disease in users of OC's and estrogens. In one study, increased risk appeared after 2 years' use and doubled after 4 or 5 years' use. In one of the other studies, increased risk was apparent between 6 and 12 months' use.

7. *Carbohydrate and Lipid Metabolic Effects*—Decrease in glucose tolerance has been observed in a significant percentage of patients on OC's. For this reason, prediabetic and diabetic patients should be carefully observed while on OC's. Increases in triglycerides and total phospholipids have been observed in patients on OC's. Three studies were performed with Triphasil and no significant alterations in lipid metabolism were noted except for a slight increase in triglyceride levels in 1 study. Clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure*—Increase in blood pressure has been reported in patients on OC's. In some women, hypertension may occur within a few months of beginning OC's. In the 1st year of use, prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. Prevalence in users increases, however, with longer exposure, and in the 5th year of use is 2½ to 3 times the reported prevalence in the 1st year. Age is also strongly correlated with development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure on OC's. Hypertension that develops as a result of taking OC's usually returns to normal after discontinuing the drug.

9. *Headache*—Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of OC's and evaluation of the cause.

10. *Bleeding Irregularities*—Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing OC's. In breakthrough bleeding, as in all cases of irregular vaginal bleeding, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another OC may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase risk of thromboembolic disease. Women with past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuing OC's. Women with these preexisting problems should be advised of this possibility and encouraged to use other methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy*—Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding*—OC's given in the postpartum period may interfere with lactation and decrease quantity and quality of breast milk. Furthermore, a small fraction of the hormones in OC's has been identified in the milk of mothers on OC's; effects, if any, on the breast-fed child have not been determined. If feasible, defer OC's until infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OC's. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Pap smear and relevant laboratory tests. As a general rule OC's should not be prescribed for longer than 1 year without another physical examination and Pap smear.

2. Under influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size.

3. Patients with history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while on OC's should stop OC's and use an alternate method to try to determine whether the symptom is drug-related.

4. OC's may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency.

5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while on OC's. If jaundice develops, OC's should be discontinued.

6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution.

7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. Clinical significance is undetermined.

8. Serum folate levels may be depressed by OC's. Since the pregnant woman is predisposed to development of folate deficiency and incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OC's, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency.

9. The pathologist should be advised of OC therapy when relevant specimens are submitted.

10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OC's.

a. Increased sulfobromophthalein retention.

b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered.

d. Decreased pregnanediol excretion.

e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling.

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis—See Warnings section for information on carcinogenesis.

Pregnancy—Category X. See Contraindications, Warnings.

Nursing Mothers—See Warnings.

Adverse Reactions—An increased risk of these serious adverse reactions has been associated with use of OC's (see Warnings): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies. There is evidence of an association between the following conditions and use of OC's although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients on OC's and are believed to be drug-related. Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea, amenorrhea during and after treatment, temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement, and secretion; change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening), intolerance to contact lenses. The following adverse reactions have been reported in users of OC's, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OC's by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—For maximum contraceptive effectiveness, Triphasil must be taken exactly as directed and at intervals not over 24 hours. (If Triphasil is first taken later than first day of first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of use. Possibility of ovulation and conception prior to initiation of medication should be considered.)

Any time patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another contraceptive method until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information in package insert.

Anal submucosal injection: A new route for drug administration in pelvic malignancies

IV. Submucosal anal injection in the treatment of cancer of uterine cervix—Preliminary study

Ahmed Shafik, MD

Cairo, Egypt

Seven patients with advanced cancer of the uterine cervix were treated by anal submucosal injection of methotrexate. Each course consists of five injections, one every 5 days; each injection contains 100 mg of methotrexate. The course was repeated at 3-week intervals and was given on an outpatient basis. Investigations were performed before, during, and after treatment. Methotrexate blood level was measured 4 and 24 hours after administration. Complete response occurred in all seven patients. Relapse occurred in four but could be controlled by further methotrexate administration. Average duration of survival is 46½ months. No side effects were encountered as a result of a low methotrexate serum level that was recorded 4 hours after administration, 0.82 μmol after anal injection compared with 2.8 μmol for the intravenous route. The beneficial effect seems to be the result of the high methotrexate concentration in uterine and tumor tissue. The route adopted by the drug to reach the uterus from the anal submucosa is through the hemorrhoidogenital communicating veins. This preliminary study demonstrates that anal injection of methotrexate is effective in the treatment of advanced cervical cancer. It is safe, well tolerated, and can be used as an outpatient treatment. (Am J Obstet Gynecol 1989:161:69-72.)

Key words: Uterine cervix, cancer, treatment, methotrexate, uterine cervix cancer

Patients with advanced cancer of uterine cervix have a poor prognosis, with a 5-year survival rate of 30% in International Federation of Gynecology and Obstetrics stage III and only 10% to 15% in International Federation of Gynecology and Obstetrics stage IV.[1, 2] Surgical procedures for these advanced stages are mainly palliative. Likewise, radiotherapy is much less effective in the treatment of stage III and IV disease than stages I and II.

The role of chemotherapy in the treatment of advanced cancer of the uterine cervix is increasing, and there is continued interest in the development of more effective cytotoxic therapy. There are many reports on the effectiveness of chemotherapy in squamous cell carcinoma of the uterine cervix in patients with advanced or recurrent disease who cannot be helped by surgery or radiotherapy.[3-5]

Efforts continue to improve the efficacy of cytotoxic therapy by means of altered drug doses, combination chemotherapy, and different routes of administration.

Herein are presented seven cases of advanced cancer of the uterine cervix treated with methotrexate administered by the submucosal anal route.

From the Department of Surgery, Faculty of Medicine, Cairo University.

Physioanatomic considerations

A recent study[6] has shown that the hemorrhoidal venous plexus communicates with the urogenital plexus by two to six communicating veins called "hemorrhoidogenital veins." The latter are unidirectional, transmitting the blood from the hemorrhoidal to the urogenital plexus, but not in the reverse direction.

Injection of a radiopaque dye into the submucosa of the anal canal led to visualization of the urinary bladder, uterus, and vagina.[6] Thus anal cystography[7] and anal cystovaginohysterography[8] could be achieved by this route. Further studies have demonstrated that the urinary bladder after injection of misonidazole (a radiation sensitizer) into the anal submucosa showed a concentration of the drug as high as eight times the serum level,[9] whereas the uterus showed 10 times concentration (Shafik A, El-Desouky G. Unpublished observations).

The submucosal anal route is being used to administer drugs for pelvic malignancies and other pathologic conditions. It has been used for the treatment of advanced bladder cancer with encouraging results.[10] It is also used in the treatment of chronic relapsing prostatitis (Shafik A. Unpublished observations).

These findings prompted me to use the submucosal

anal route for methotrexate administration in the treatment of advanced cancer of the uterine cervix. This procedure aims at inducing a high methotrexate concentration in the uterine cervix with a minimum serum level, thus attaining a high therapeutic result and minimal side effects. The results of treatment of seven patients via this route are herein presented.

Case reports

Case 1. A 63-year-old patient had advanced cervical carcinoma (stage IIIB). She had received radiation therapy to the pelvis for a total dose of 6000 rads and cisplatin with no response. Examination of the cervix showed that a large mass, 5 by 3 by 3 cm, replaced the cervix and encroached on the upper 2 cm of the vagina. Biopsy examination showed that the tumor was a squamous cell carcinoma of the large cell and nonkeratizing type. Sonography revealed enlarged iliac and obturator glands. Hematologic reserve and renal and hepatic functions were adequate.

Six courses of methotrexate were given by the submucosal anal route starting in June 1982. Each course consisted of five injections of methotrexate. One injection was given every 5 days; each injection contains 100 mg of methotrexate. The course was completed in 25 days and was followed by a 3-week interval of rest before the next course was started. Routine hematologic assessment was performed before each injection. Serum methotrexate level was assessed 4 and 24 hours after administration. The patient received the treatment on an outpatient basis.

Follow-up examination was comprised of pelvic sonography and cervical tumor biopsy studies performed every 3 months for the first year, every 6 months for the second year, and annually thereafter or on a report of vaginal bleeding. Computed tomography scan of the abdomen and chest x-ray studies were done every 6 months for 1 year and every year thereafter.

During the third course, the patient had nausea and vomiting that were controlled by medical measures without discontinuation of treatment. Hematologic reserve and renal and liver functions remained almost unchanged throughout the period of treatment. Methotrexate blood levels 4 and 24 hours after injection recorded 0.75 and 0.00 μmol, respectively. After the fourth course, the tumor disappeared completely, and cervical biopsy findings were negative. Sonography showed disappearance of iliac and obturator nodes. The patient has survived now 5½ years with no evidence of recurrence.

Case 2. A 69-year-old woman had stage III cervical cancer. Examination revealed an exophytic mass 4 by 3 by 3 cm, which occupied the uterine cervix and involved the two lateral vaginal fornices. Pelvic examination revealed induration in the right parametrial region proved by computed tomography scan to have the size of 3.5 by 2 by 1.5 cm. Biopsy studies of the cervical mass showed small cell, nonkeratizing, squamous cell carcinoma.

When the patient showed no response to radiation therapy to the pelvis (total dose, 6000 rads), she was given six courses of methotrexate injected per anus in the aforementioned dose. The first course was given in March 1983. The patient was assessed and followed up by pelvic sonography, cervical tumor biopsy studies, and computed tomography scan. Methotrexate serum level was measured 4 and 24 hours after injection.

No side effects from the drug were encountered. Methotrexate serum levels were 4 and 24 hours after injection 0.65 and 0.00 μmol, respectively. After the third course of methotrexate treatment, the cervical mass and parametrial induration disappeared. At the end of the fifth course, cervical biopsy findings were negative and computed tomography scan recorded disappearance of the parametrial mass. Cervical tumor relapse occurred 8 months after termination of the sixth course. The patient received three additional

courses of methotrexate by the submucosal anal route. She has now survived for 56 months and is free of malignancy.

Case 3. A 56-year-old woman had a huge 6 by 3 by 3 cm mass that replaced the entire uterine cervix and encroached on the upper half of the vagina. The mass was fixed to the urinary bladder anteriorly and the anal canal posteriorly. Bilateral parametrial induration was confirmed by computed-tomography scan. Biopsy studies showed that the tumor was poorly differentiated squamous cell carcinoma.

Cystogram revealed that the tumor was encroaching on the urinary bladder. One year before presentation, the patient received 6000 rads to the pelvis with no response. Combination chemotherapy of cyclophosphamide, methotrexate, and mytomycin C also proved to be ineffective.

The first course of methotrexate, which was administered per anus, was given in April 1983. There were no side effects. Methotrexate serum level 4 and 24 hours after injection was 1.0 and 0.10 μmol, respectively. The patient completed six courses. By the end of the fourth course, the cervical mass and parametrial induration disappeared. The results of the cervical biopsy examination were negative after termination of the sixth course.

In July 1986, cervical recurrence occurred as shown by biopsy studies. A negative biopsy finding was obtained after four courses of methotrexate, and the patient is alive and tumor free since then.

Cases 4 to 7 (Table I). Four female patients, ranging in age from 48 to 72 years, had stage III squamous cell carcinoma of the uterine cervix. Their data are shown in Table I. They were managed in the same way as the aforementioned cases. All had negative cervical biopsy results by the end of the sixth course of methotrexate injection. Recurrence occurred in two patients 10 and 14 months after termination of the six courses. Three additional methotrexate courses were given, of which the cervical biopsy findings of the two patients at the end of treatment were again negative. The four patients have now survived 46, 41, 33, and 29 months since the start of treatment and are tumor free.

Technique of anal submucosal injection. The 100 mg methotrexate vial is diluted with 10 ml of saline solution. The usual 10 ml capacity syringe is used for injection. Anesthesia is not required, since the procedure is painless. With the patient in the lithotomy or left lateral position, a proctoscope is introduced, the anal canal is inspected, and the pectinate line is identified. Injection is done in the submucosa of the anterior wall of the anal canal above this line. The mucosa at the proposed site of injection is swabbed clear with a pledget of cotton wool on forceps. The needle is then inserted obliquely through the mucosa.

A small amount of methotrexate solution is injected. If the mucosa balloons up in an edematous wheal with obvious vessels crossing it, this indicates that the fluid is spreading in the submucous plane as desired. If no wheal is produced, the needle is too deep and should be gradually withdrawn with simultaneous, repeated injections of minimal amounts of the fluid until the effect described is achieved. A dead white mucosa at the injection site signifies that the fluid is being injected into the mucosa itself. When the proper submucosal plane is reached, the rest of the solution is then injected.

Methotrexate assay. Blood methotrexate was estimated by an enzyme immunoassay kit obtained from Syva, (California). Blood samples were withdrawn 4 and 24 hours after methotrexate injection. They were centrifuged at 1500 *g*, and sera were subjected immediately to the assay. Methotrexate concentrations were expressed in micromoles.

Comment

The present results show that complete response occurred in all seven patients treated with methotrexate injected by the submucosal anal route. However, relapse occurred in four of seven patients 8 to 30 months after termination of treatment (average, 15½ months). It could be controlled by the administration of further courses of methotrexate (average, three). The duration of survival from the start of treatment varied from 29 to 66 months, with an average of 46½.

Investigators reported objective responses in 10% to 25% of patients with cervical cancer for 4 to 6 months when single chemotherapeutic agents were used.[11, 12] More recently the Gynecologic Oncology Group reported a response rate of 38% for cisplatin in squamous carcinoma of the cervix[13] and 31% for bleomycin.[14] Good response rates have been reported for several combination chemotherapy regimens. A response rate of 89% was obtained with a combination of cisplatin, bleomycin, and methotrexate,[15] and 77% was obtained with a combination of cisplatin, bleomycin, and mitomycin C.[16] However, the responses were of short duration and drug toxicity was significant.[15, 16]

No side effects were encountered in these seven patients. Only one patient had nausea and vomiting which could be controlled without discontinuation of treatment. The absence of toxic manifestations is the result of the low methotrexate serum level obtained by the submucosal anal route compared with the intravenous route, the average after 4 hours was 0.82 μmol for the former and 2.8 μmol for the latter.[10] The difference is highly significant. Furthermore, the serum levels obtained 24 hours after methotrexate injection (mean, 0.66 μmol) indicate that there is no cumulative effect of methotrexate in the circulation.

The beneficial effects of anal injection of methotrexate seem to be the result of the high drug concentration in uterine and tumor tissue. A recent experimental study has shown that carbon 14–labeled misonidazole concentration in uterine tissue after anal injection was 10 times that of serum 15 minutes after injection (Shafik

A, El-Desouky G. Unpublished observations). Measurement of methotrexate level in cervical tumor tissue after various routes of administration is being performed and will be reported in a separate communication.

The route adopted by methotrexate to reach the uterine cervix from the anal submucosa needs to be discussed. Recent studies have shown that when a radiopaque dye was injected in the anal submucosa, it was absorbed by hemorrhoidogenital lymphatics and veins and reached the uterovaginal plexus.[6, 8] Anal injection of methotrexate seems to follow the same route and reaches the uterus in concentrations high enough to effect tumor regression.

In conclusion, the present study demonstrates that methotrexate anal injection is effective in the treatment of cervical cancer. It is safe, well tolerated, and used on an outpatient basis. A further advantage of this route is that it allows for the administration of much greater drug doses than the intravenous route without the threat of toxicity. The maximal drug concentration is in the tumor rather than in the blood.

Admittedly, the number of patients in this communication is small, but the results warrant publication as a preliminary study.

The valuable assistance of Mrs. Margot Yehia in revising the manuscript is highly appreciated.

Aggressive angiomyxoma first diagnosed as levator hernia

Gregory P. Sutton, MD,[a] Robert E. Rogers, MD,[a] Lawrence M. Roth, MD,[b] and Clarence E. Ehrlich, MD[a]

Indianapolis, Indiana

When a 32-year-old woman was first seen, physical findings suggested she had a large levator hernia, but at the time of surgical resection an aggressive angiomyxoma was found. (AM J OBSTET GYNECOL 1989;161:73-5.)

Key words: Angiomyxoma, levator hernia

Aggressive angiomyxoma is a benign but locally aggressive neoplasm seen almost exclusively in the pelvis or perineum of premenopausal women.[1, 2] The tumor in this case was initially diagnosed as a levator sling hernia. A pelvic computerized axial tomogram helped to clarify the diagnosis and to direct surgical excision.

Case report

I. W., a 32-year-old white woman (para 2-0-0-2) was referred to Indiana University Medical Center because of a large, soft mass of the left vulva and buttock. The patient noticed asymmetry of her left buttock shortly after she was uneventfully delivered of her second child in November 1981. On standing, the mass protruded into the left buttock and was accompanied by a progressive traction sensation in the lower abdomen. She had no associated bowel complaints but did have progressive urinary frequency. She was thought to have a levator or perineal hernia, and was referred for evaluation in June 1987.

The patient was a healthy-appearing postal worker whose physical examination results were normal. On pelvic examination a 6 × 8 cm protuberant soft mass was identified arising from the anterior left buttock and labium majus (Fig. 1). The mass could be easily reduced through a palpable 7 cm defect in the left midlevator plate and gave the impression of a hernia. The uterus was retrodisplaced, and there was a mass sensation on bimanual examination.

A computerized tomogram showed an 11 × 8 cm well-demarcated mass that extended from the pelvis to the left buttock. There was a central, cleft-like hypodense area, but no fat density was observed (Fig. 2). An intravenous pyelogram demonstrated moderate hydronephrosis on the right side, marked displacement of the bladder to the right, and deviation of the left ureter across the midline of the pelvis (Fig. 3).

Fig. 1. Appearance of mass distorting left labium majus and buttock.

A biopsy specimen obtained through the left side of the vagina showed myxomatous and vascular components diagnostic of aggressive angiomyxoma, and the next day the large mass was completely resected using a combined abdominoperineal approach. The reproductive organs were preserved. The patient did well and had no evidence of disease 1 year postoperatively.

Estrogen and progesterone receptor content were determined with a dextran-coated charcoal assay. The estrogen receptor level was 29.4 femtomoles/mg of protein and the progesterone receptor level was 5.2 femtomoles/mg of protein; both were intermediate levels.

Pathology

Gross and microscopic findings. On gross examination the specimen was soft, easily compressible, and somewhat fleshy in consistency. The cut surface of the tumor was circumscribed, soft, gray-white, homogeneous, gelatinous, and moist (Fig. 4).

Histologically, the tumor was circumscribed and was

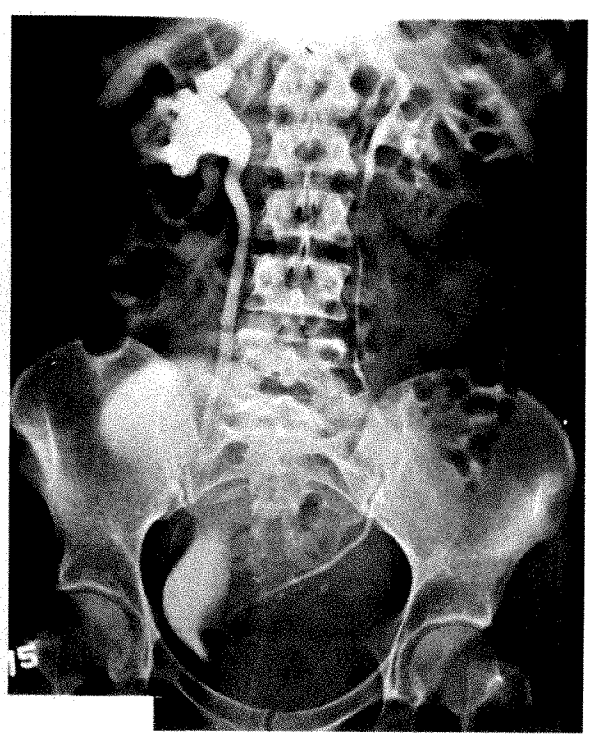

Fig. 3. Intravenous pyelogram demonstrates marked displacement of bladder and left ureter and right hydronephrosis.

confined by a condensation of eosinophilic stromal material and tumor cells. Two distinct components were seen. The first, a loosely textured myxomatous component, contained bipolar to multipolar mesenchymal cells with small uniform vesicular nuclei with an occasional small inconspicuous nucleolus, but lacking mitoses. Interspersed throughout the myxomatous matrix were small to medium-sized vessels, some of which were thin-walled and resembled capillaries, whereas others had thick muscular walls. In some areas around medium-sized muscular blood vessels, slips of smooth muscle were observed within the myxomatous stroma. No small nerves were noted within the tumor.

Comment

This case was, for the most part, a typical aggressive angiomyxoma, although it was better circumscribed than many of the reported cases. Although multiple small nerves have been found within the myxoid stroma of several of the tumors, this case is the first in which fascicles of smooth muscle cells were present focally within the stroma.

The ultrastructural features of the neoplasm were similar to those of the previously studied cases. Steeper and Rosai[1] coined the term "aggressive angiomyxoma" in 1983 to describe nine cases of a benign but locally infiltrative neoplasm that arose in the pelvis or perineum of women who ranged from 21 to 38 years of age. The next year Begin and associates[2] reported nine additional cases including two tumors that arose in male patients and one in a 63-year-old woman. These masses were alternatively diagnosed as Bartholin cysts or neoplasms, vaginal prolapse, or hernias of the pelvic floor or obturator fossa. The history and physical findings in the current case were strongly suggestive of a levator hernia. Computed tomographic findings, however, suggested the diagnosis of aggressive angiomyxoma. These

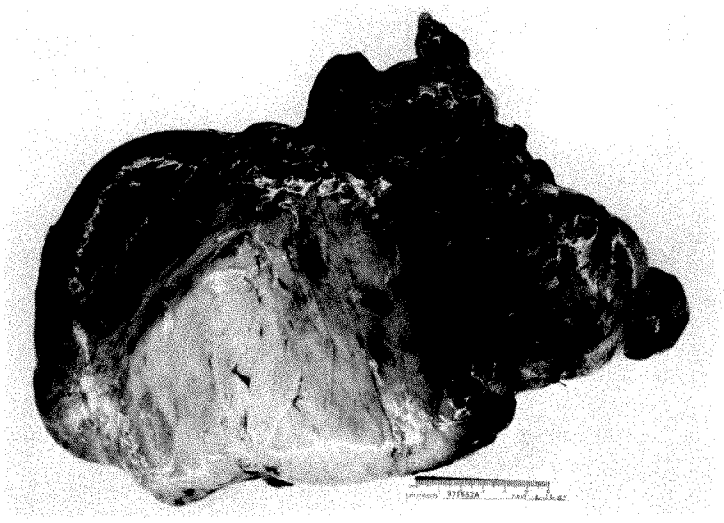

Fig. 4. Cut surface of neoplasm was homogeneous, moist, and gelatinous.

findings underscore the importance of radiographic evaluation before operation for suspected perineal or levator hernias.

Local infiltration of these tumors is characteristic, although they may be clearly demarcated in some areas. Infiltration into skeletal muscle and fat has been observed. Local recurrences at intervals from 9 to 180 months were reported in 10 of the 18 cases reported by Steeper et al.[1] and Begin et al.[2] All were thought to be a result of an inadequate primary excision. No metastases or deaths have been described.

Aggressive angiomyxoma must be distinguished from a variety of similar neoplasms including myxoid lipoma and liposarcoma, soft tissue myxoma, nerve sheath tumor, myxoid neurofibroma, embryonal rhabdomyosarcoma, malignant fibrous histiocytoma, and fibromatosis with focal myxoid areas.

Vulvar, pelvic, or perineal masses that are soft and slow growing must be evaluated with the diagnosis of aggressive angiomyxoma in mind so that adequate extirpative surgery may be performed and recurrences obviated. The presence of estrogen and progesterone receptor protein suggests a possible role for hormonal therapy in those cases that cannot be completely removed.

Asymptomatic thrombocytopenia associated with chorioangioma of placenta

Nirmala S. Limaye, MD, and Jean-Gilles Tchabo, MD
Arlington, Virginia

Chorioangioma is a common primary tumor of the placenta. Most tumors are small and are only detected by careful sectioning of the placenta. Large tumors can be diagnosed antenatally by ultrasonography and may result in maternal and fetal complications. (AM J OBSTET GYNECOL 1989;161:76-7.)

Key words: Chorioangioma, maternal complication

A case of chorioangioma, a common primary tumor of the placenta, is reported. A healthy male infant was delivered by cesarean section.

Case report

R. B., a 21-year-old woman, gravida 2, para 1, aborta 0, whose last menstrual period was May 1, 1987, was admitted in December 1987 for mild pelvic pain and urinary frequency. The patient had an unexplained stillbirth at 38 weeks' gestation on June 8, 1986. Autopsy revealed a normal fetus and placenta.

The current pregnancy was uneventful until December 7 when results of a routine blood count indicated platelets at 117,000/mm^3. The coagulation profile showed fibrin split products >40 and <80, but normal fibrinogen, partial thromboplastin time and prothrombin time levels. An ultrasonogram revealed a male fetus of 33 weeks' gestation with no congenital anomalies (Fig. 1). The placenta was anterior and a 5.5 cm sonolucent subchorionic necrotic lesion was noted with a normal amount of amniotic fluid.

A nonstress test on admission was reactive. Repeat ultrasonography placed the fetus at 35 to 36 weeks' gestation with estimated fetal weight of 6 pounds; the mass was unchanged.

The platelet count was 107,000/mm^3 and the hematocrit was 34. Fibrin split products were >80 but <160; fibrinogen, partial thromboplastin time, and prothrombin time levels were normal.

On December 29 the platelet level dropped to 102,000/mm^3 and hemoglobin to 10 gm; the urine culture grew streptococci.

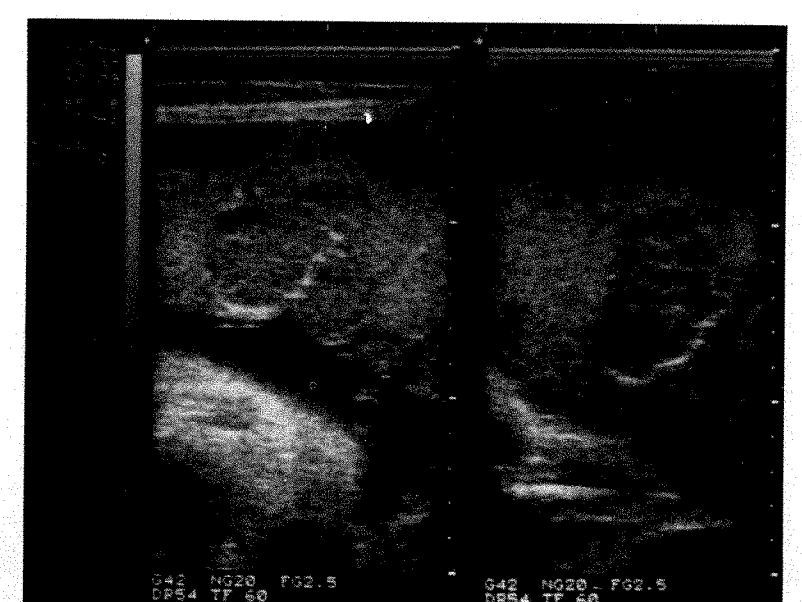

Fig. 1. Sonogram showing male fetus at 33 weeks' gestation with no congenital anomalies.

A healthy male infant with 1- and 5-minute Apgar scores of 8 and 9, respectively, and a birth weight of 5 pounds 11½ ounces was delivered by cesarean section with normal cord pH. The placenta was delivered with a 5 cm loose homogeneous mass.

The patient did well after operation except for a low-grade fever that was treated with intravenous ampicillin. The infant had mild respiratory distress with pneumonitis and was treated with intravenous antibiotics.

Histologic examinations of the placenta showed normal villous pattern. Sections through the mass revealed benign chorioangioma.

Comment

Chorioangioma, the most common tumor of the placenta, was described by John Clarke in 1798. The incidence of small tumors is between 1:70 and 1:100, but large chorioangiomas are reported in only 1:9000 deliveries. These tumors appear as homogeneous, firm, rubbery masses. Histologically they appear as well-differentiated capillary patterns; whether this represents a true neoplasm or hamartoma is uncertain.

Larger chorioangiomas cause maternal and fetal complications such as toxemia, abruptio placentae, premature labor, hydrops, fetal malformations, fetal thrombocytopenia, and angiomas of the skin. Easy diagnosis by ultrasonography has been reported.[1,2]

Maternal asymptomatic thrombocytopenia with mild coagulopathy was noted in our case. Both were probably triggered by necrosis and infarction of the chorioangioma.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1989 issues from the Publisher, at a cost of $56.00 ($79.00 international) for Vol. 160 (January-June) and Vol. 161 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C.V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

First-trimester and early second-trimester diagnosis of nuchal cystic hygroma by transvaginal sonography: Diverse prognosis of the septated from the nonseptated lesion

M. Bronshtein, MD, S. Rottem, MD, N. Yoffe, MD, and Z. Blumenfeld, MD
Haifa, Israel

Fetal cystic hygroma is a congenital malformation of the lymphatic system appearing as a single or multiloculated fluid-filled cavity, most often in the nuchal region. The malformation is believed to arise from failure of the lymphatic system to communicate with the venous nuchal system. Sometimes the lesion progresses to fetal hydrops, causing fetal death. To further delineate the cause and natural history of this disorder, we have prospectively studied eight cases of cystic hygroma of the neck, detected at gestational ages of 9 to 15 weeks by transvaginal sonography. Three of the eight fetuses survived (37.5%) and were normal at birth. Either hydrops fetalis or intrauterine fetal death occurred in the other five fetuses. In one of these five, therapeutic abortion was induced because of trisomy 21. In another fetus of these five, trisomy 18 was diagnosed by amniocentesis. This pregnancy ended in intrauterine fetal death. The ultrasonic evaluation of the cystic hygromas revealed that those that were reabsorbed in the three ultimately normal viable fetuses were nonseptated cysts, whereas all the four cystic hygromas ending in fetal death or associated with aneuploidy were septated, multilocular hygromas. In another fetus with nonseptated hygroma, nonimmune hydrops developed, which resulted in premature delivery and early neonatal death. (AM J OBSTET GYNECOL 1989;161:78-82.)

Key words: Fetal cystic hygroma, nuchal hygroma, transvaginal sonography, first-trimester diagnosis

Cystic hygroma is a congenital malformation of the lymphatic system, which can be generalized or localized most often in the nuchal area.[1-5] This malformation is often associated with chromosomal aneuploidies, especially Turner's syndrome, in which case it has a poor prognosis.[1-3, 6] Smith[7] and Graham et al.[8] have proposed a mechanism of lymphatic maldevelopment that explains both cystic hygromas and hydrops in fetuses and neck webbing and peripheral edema in adults with Turner's syndrome.[2] Substantiation of their hypothesis, termed the *jugular-lymphatic obstruction sequence*, and further karyotype studies have been limited because only abortuses could be evaluated previously.[2] The ability to diagnose fetal malformations by first-trimester transvaginal sonography allows for the early recognition of cystic hygromas and follow-up of their development or reabsorption and for detection of generalized hydrops and/or lymphedema[9, 10] associated with nuchal cystic hygroma.

We report eight cases of nuchal cystic hygromas, five of which ended in fetal or early neonatal death, whereas in the other three the hygromas disappeared and the gestations generated normal term fetuses.

Material and methods

During the past year, from September 1987 to August 1988, the diagnosis of cystic hygroma of the neck was made by first-trimester or early midtrimester transvaginal sonography in eight fetuses. These eight cases of cystic hygroma were diagnosed among 800 patients routinely evaluated at 9 to 15 weeks of gestation for detection of fetal malformations. Equipment used in the study included the Elscint ESI-1000 ultrasound imaging system (Elscint Inc., Boston) with a 6.5 MHz vaginal probe (ESI ED-65 TV), which consisted of a mechanical sector scanner with an oscillating transducer, and a 3.5 MHz abdominal probe (ESI ED-35). Gestational age was determined by crown-rump length, biparietal diameter, head circumference, abdominal circumference, and femur length measurements, in conjunction with menstrual or ovulation dating.[9] A careful sonographic search for other malformations or anatomic abnormalities was conducted in each case.[9, 10] If sufficient amniotic fluid was present, amniocentesis was performed, in each case of cystic hygroma, to determine the fetal karyotype. The α-fetoprotein concen-

6	27	G1P0	14	Nonseptated	46,XY	Normal term neonate, 3000 gm male
7	30	G2P1	15	Nonseptated	46,XX	Normal term neonate, 3100 gm female
8	33	G2P1	12	Nonseptated	46,XY	Nonimmune hydrops, premature delivery at 30 wk; early neonatal death

tration in the amniotic fluid was measured by radioimmunoassay, and karyotypes were obtained from amniocytes or from peripheral lymphocytes obtained from cord blood at delivery or after therapeutic abortion (cases No. 1 and 5 through 8).

Results

The eight cases of cystic hygroma of the neck were diagnosed out of about 800 gestations carefully evaluated at 9 to 15 weeks of pregnancy for detection of malformations (1%) (Table I). Cervical cystic hygroma was the second most common malformation detected in this series, the central nervous system malformations being the most prevalent (10 of 800 cases, 1.25%). Gestational age at the time of diagnosis ranged from 9 to 15 weeks (from last menstrual period). In four of the eight cases (50%), the cervical cystic hygroma was septated and multiloculated. In two of them (cases No. 1 and 2), early fetal death occurred at 11 and 16 weeks, respectively, within 2 weeks of diagnosis; hydrops fetalis developed in the latter before fetal death. In the third case, diagnosed at 11 weeks of gestation in a 33-year-old white woman, gravida 3, para 2, amniocentesis was performed at 16 weeks and again, because of a lack of growth in the amniocytes, at 20 weeks. Trisomy 21 was diagnosed and therapeutic abortion was done at 24 weeks' gestation. The female abortus showed the phenotype of trisomy 21 (this was reestablished by karyotyping of fetal lymphocytes).

The fourth case of septated cystic hygroma was diagnosed in a 40-year-old white woman. The pregnancy was induced by human menopausal gonadotropin–human chorionic gonadotropin and multiple malformations including hydrops fetalis, short fetal bones, pleural effusion, triangulocephaly, clubfoot, and septated cervical cystic hygroma were diagnosed by transvaginal sonography at 15 weeks since the last menstrual period. At this time fetal biparietal diameter, femur length, abdominal circumference, and head circumference measurements were consistent with those of a 12-week-old fetus. The results of transvaginal sonographic scanning were suggestive of aneuploidy, and trisomy 18 was diagnosed by amniocentesis. Hydrops fetalis developed at 15 weeks and fetal death occurred 2 weeks later.

In the other four cases, nonseptated posterior cervical cystic hygromas were detected at 12 to 15 weeks since last menstrual period. Amniocentesis in all these four cases (cases No. 5 to 8) revealed normal karyotypes and normal levels of α-fetoprotein. Sonographic follow-up revealed absorption of the cystic hygromas, with apparent communication of the cystic lesion with the lumen of the internal jugular vein (Figs. 1 and 2). The cystic hygromas developed into webbed neck (Fig. 3) and gradually disappeared. The karyotype in three of the fetuses was 46,XY and in one was 46,XX without mosaicism. Three pregnancies resulted in normal term neonates, two boys and one girl (without cervical hygroma or webbed neck). The other pregnancy (case No. 8) resulted in a fetus with nonimmune hydrops who was delivered at 30 weeks and died 2 days later at another hospital. No other malformations were described.

Comment

Cystic hygromas are believed to develop from a defect in the formation of lymphatic vessels.[1,2] The fetal lymphatic vessels normally drain into two large sacs lateral to the jugular veins.[2] These jugular lymph sacs

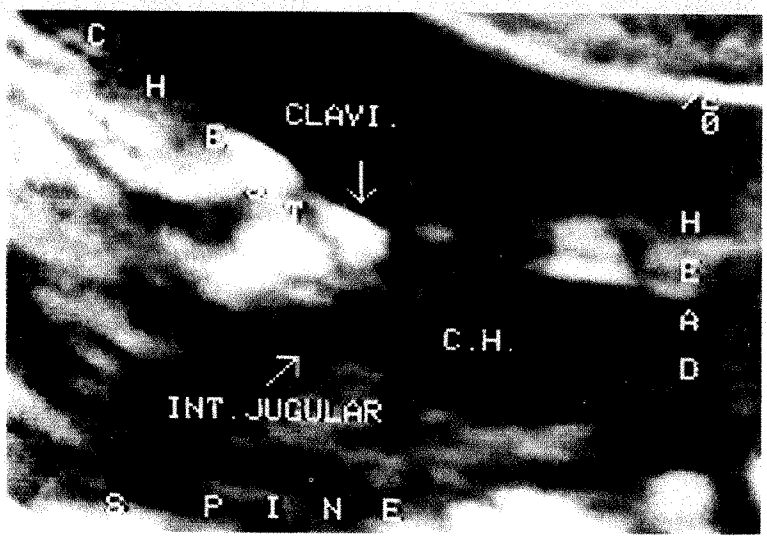

Fig. 1. Cystic hygroma of 14-week-old male fetus (case No. 5), ultimately born normal. Note communication between cystic hygroma *(C.H.)* and lumen of internal jugular vein *(INT. JUGULAR)*. Fetal head, spine, chest, and clavicle *(CLAVI)* are marked.

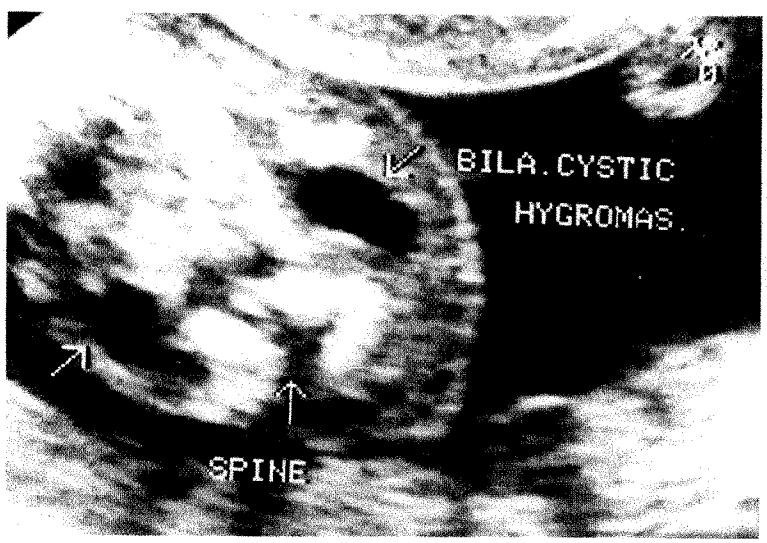

Fig. 2. Transverse scan of fetal neck obviating bilateral nonseptated cystic hygromas at 14 weeks of pregnancy (case No. 6). The nonseptated hygromas were resolved later in pregnancy and a normal male fetus was born at term.

eventually form communications with the venous system and become the terminal portions of the right lymphatic duct and the thoracic duct (Fig. 1). If lymphatic and venous structures fail to communicate, the jugular lymph sacs enlarge and lymph accumulates in tissues.[2] Cystic hygromas of the posterior triangles of the neck (Fig. 2) and hydrops result.[2, 10, 11] If the jugular lymph sacs and the jugular veins then connect or an alternative route of lymphatic drainage develops before intrauterine death, the cystic hygromas regress and peripheral edema may resolve.[2] We believe this sequence of events occurred in three of the cases in our small series (cases No. 5 through 7), and the birth of normal fetuses resulted. The above sequence of embryologic events comprises the jugular-lymphatic obstruction sequence described by Smith[7] and Graham et al.[8]

Two observations corroborate these ideas. Lymphangiography performed on adults with Turner's syndrome demonstrates hypoplasia of peripheral lymphatics in this disorder[12] and raises the possibility that lymph may find an alternative direct route to the venous system while still in the extremities.[2, 13] In addition,

Fig. 3. Transverse scan of fetal neck at 16.5 weeks by transvaginal sonography delineating very thick (9.2 mm) nuchal fold in case No. 5.

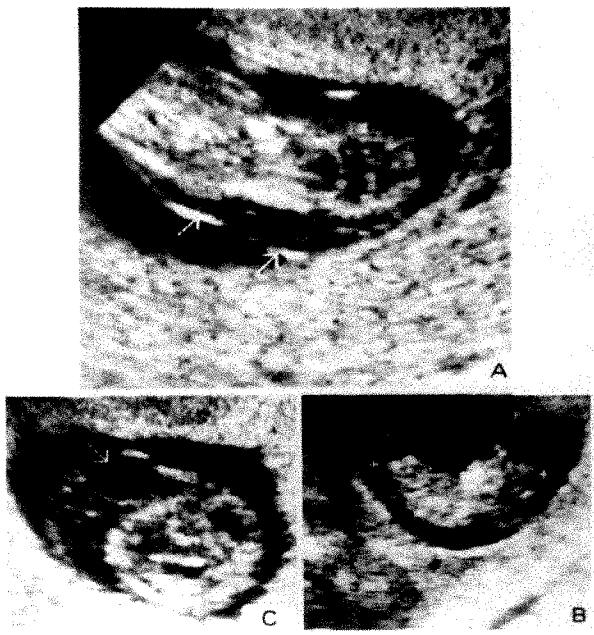

Fig. 4. Septated cystic hygroma in a 9.5-week-old fetus (case no. 1) where the lesion is clearly visualized by transvaginal sonography on longitudinal section **(A)** and on transverse section **(C)** but not detected by transabdominal scan **(B)**. *Arrows* point to the lesion on transvaginal sonography.

Shaub et al.[14] have described a fetus with a unilateral left cystic hygroma and edema of all body parts except the right arm.[2] This pattern suggests that the jugular lymph sac and the thoracic duct that empties into it were obstructed, whereas there was adequate drainage of the right lymph sac and its tributaries.[2] Besides Turner's syndrome, several other congenital malformation syndromes have been reported in association with fetal cystic hygromas, neck webbing (Fig. 3), or redundant posterior neck skin after birth.[1,2] These include Noonan's syndrome, fetal alcohol syndrome, distichiasis-lymphedema syndrome, familial pterygium colli, and several chromosomal aneuploidies: trisomy 18, trisomy 21, 13q-, and 18p-, partial 11q/22q trisomy, trisomy 22 mosaicism, 45,X/46,XX mosaicism, and 47,XXY.[1,2] In our small series 50% of the fetuses had normal karyotype.

The incidence of this malformation at the end of the first trimester to the early midtrimester is around 1% (8 in 800). This disparity is understandable when one takes into consideration the high rate of intrauterine death that occurs in those cases in which hydrops fetalis develops on one side and the spontaneous absorption of those hygromas in eukaryotic fetuses, in whom lymphatic-venous communications develop, on the other side. Previous studies accentuated the grave prognosis in the cases in which the cystic hygroma is associated with hydrops but claimed that only scant information existed about the prognosis in the absence of hydrops.[1,2,15] This statement was probably correct before transvaginal sonography was introduced. When transvaginal sonographic scanning was introduced at the end of the first trimester to the beginning of the midtrimester, it enabled the detection of 30 fetal malformations as early as 9 weeks after the last menstrual period. This relatively new technology enabled us to detect eight cases of fetal cystic hygroma among 800 gestations (1%) routinely scanned for the early detection of fetal malformations. We believe that about 37% of the early detected cystic hygromas, especially the nonseptated ones, bear a good prognosis, according to our small series. Moreover, one of the cases in which cystic hygroma of the neck was diagnosed had undergone abdominal sonographic evaluation without detection of the malformation (case No. 1, Fig. 4).

All the cases in our series of septated cystic hygroma ended in fetal death and/or aneuploidy, whereas 75% (3 of 4) of the cases with a nonseptated lesion resulted in delivery of normal neonates. This may suggest two possible explanations to the diverse prognosis:

1. The septated hygromas, which are also the nuchal ones, may consist of a different category from the nonseptated lesions, which are the more lateral ones and bear a better prognosis; or

2. The septated lesions are associated with complete obstruction of the cervical lymphatic sacs from the communication with the jugular venous system, and the accumulating lymphatic fluid dissects between the cervical tissues creating multilocular cysts. Later, the further accumulating lymph may create subaxillary cystic lesions (observed in one of our cases) and ultimately generalized fetal hydrops (as in cases No. 1, 2, 4, and 8 in our series) (Fig. 5). The nonseptated hygromas may represent temporary accumulation of lymph and

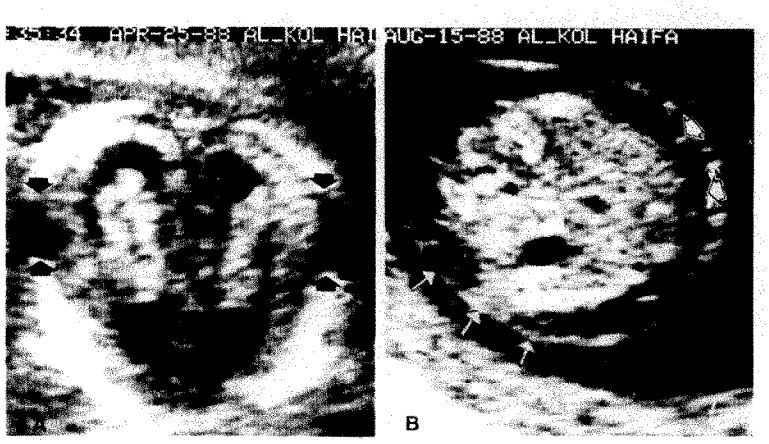

Fig. 5. Fetal hydrops. Transvaginal sonographic scan of fetal skull at 15 weeks (fetus in case No. 2). **A,** Brain edema is diagnosed by relatively big "windows" at lateral sutures of skull *(arrows)* and hyperechogenicity of brain. Choroid plexus appears normal (transverse section). **B,** Fetal hydrops and subcutaneous lymphedema by transvaginal sonographic scan of upper abdominal area. *Arrows* delineate subcutaneous septations caused by generalized lymphedema.

therefore enlargement of the lymphatic sacs lateral to the jugular veins. The increased pressure resulting from this temporary lymph accumulation may overcome an incomplete obstruction between these lymphatic sacs and the jugular veins and result in gradual disappearance of these enlarged sacs. One may speculate that whereas the complete obstruction is associated with chromosomal aneuploidy and the incomplete obstruction is associated with eukaryotic fetuses, the later may be a variant of normal physiologic embryogenesis of the lymphatic jugular venous communications (Fig. 1). In previous reports the diagnosis of cervial hygroma has been made at gestational ages older than 9 to 15 weeks, and mainly the hygromas associated with complete obstruction (septated, multiloculated) were diagnosed, which therefore resulted in a poor prognosis being given to these lesions. Since the availability of transvaginal sonographic technology, the early scanning practiced at 9 to 15 weeks of gestation has enabled the diagnosis of both types of hygromas, and enabled the distinction of "septated lesion, bad outcome" on the one hand versus "nonseptated lesion, good outcome" on the other to be made.

Until more data are collected to support the relatively good prognosis of those cases not associated with hydrops, we recommend amniocentesis for karyotyping and α-fetoprotein measurement in each case of cervical cystic hygroma.

Enlarged cisterna magna in trisomy 18: Prenatal ultrasonographic diagnosis

Amy S. Thurmond, MD[a, b] David W. Nelson, MD,[a] Richard I. Lowensohn, MD,[b] William P. Young, MD,[b] and Lowell Davis, MD[b]

Portland, Oregon

Ultrasonographic visualization of an enlarged cisterna magna was the initial clue that led to the prenatal diagnosis of trisomy 18 in five patients. Prenatal diagnosis of trisomy 18, a lethal defect, is important for proper patient counseling and management. (AM J OBSTET GYNECOL 1989;161:83-5.)

Key words: Ultrasonography, trisomy 18, cerebellum, cisterna magna

Trisomy 18 is the second most common trisomy syndrome, occurring in 0.3/1000 live births.[1,1] The prenatal diagnosis of trisomy 18 currently depends on the recognition of a constellation of subtle findings: fetal structural anomalies detected by ultrasonography, intrauterine growth retardation (IUGR), and abnormal amniotic fluid volume.[1-3] The diagnosis is then confirmed by chromosome analysis of either amniotic fluid or fetal blood.

We report the study of five fetuses in whom prenatal identification of an enlarged cisterna magna (presumably a result of cerebellar hypoplasia) caused us to search for more subtle structural fetal abnormalities, and led to the diagnosis of trisomy 18. Our results suggest that an enlarged cisterna magna may be a more specific ultrasonographic finding for diagnosis of trisomy 18.

Methods

All patients referred to our institution for ultrasonography to exclude fetal anomalies have a sector real-time ultrasound examination (Acuson, Mountainview, Calif.; ATL, Bothell, Wash.) that includes a transaxial view of the head angled 15 degrees caudal to the canthomeatal line. Measurements are taken of the transverse cerebellar diameter according to the method of McLeary et al.[4] and of the anteroposterior cisterna magna diameter according to Mahoney et al.[5] (Fig. 1).

Fig. 1 Ultrasonogram of fetus with trisomy 18 (patient No. 3) at 36½ weeks' gestation. Transducer is angled 15 degrees caudal to BPD plane. Transverse cerebellar diameter *(long arrows)* is small, and cisterna magna depth *(short arrows)* is large.

Table I. Summary of data in five fetuses with trisomy 18

	Clinical history			
Patient no.	*Maternal age (yr)*	*Gestation by dates (wk)*	*Ultrasound indication*	*Fetal monitoring*
1	32	34	PROM	Variable decelerations
2	25	36.5	IUGR(?)	
3	28	36.5	IUGR(?)	Variable decelerations
4	25	32	PROM	Variable decelerations
5	19	36.5	Fetal bradycardia	Reactive, sinus bradycardia

CI, Cephalic index = biparietal diameter/occipitofrontal diameter; *PROM*, premature rupture of membranes; *VSD*, ventricular septal defect.

Five fetuses in whom the measurements were abnormal had more detailed ultrasonographic examination, which included visualization of the hands and feet, and echocardiography. These tests are not usually performed as part of our ultrasonographic screening for fetal anomalies. Except for one patient whose labor could not be arrested, subsequent chromosome analysis of amniotic fluid or fetal cord blood was performed. All patients were delivered of their infants in our hospital, and clinical and autopsy findings were reviewed.

The five patients were seen in a 1-year period from March 1987 to March 1988. Retrospective review of all prenatal or neonatal genetic studies, and review of all deliveries for this same time period did not reveal any additional patients with trisomy 18.

Results

Results are summarized in Table I and include the gestational age of the fetus at initial examination, the indication for ultrasonography, prospective ultrasonographic findings, and the predicted biparietal diameter (BPD) determined from the measured cerebellar width.

All patients were examined in the third trimester. One patient (No. 2) was also examined at 20 weeks for confirmation of dates, at which time only mild bilateral fetal hydronephrosis was noted. Indications for ultrasonographic examination were premature rupture of the membranes (patients 1 and 4), suspicion of IUGR (patients 2 and 3), and fetal bradycardia (patient 5).

All five fetuses had small cerebella. This was concluded because the predicted BPD, which was based on the measured transverse width of the cerebellum, was smaller than the measured BPD.[4] (The BPD was thought to be reliable in all fetuses since measurements were consistent with gestational age by menstrual history and because the cephalic index was within normal limits.[6] The small cerebella were presumed not to be caused by IUGR[7] (present in fetuses 2, 3, and 4), because in fetuses without chromosomal abnormalities the cerebellar size is unaffected by IUGR.[8] All five fetuses had enlarged cisterna magnas that measured 10 to 23 mm (normal, 5 ± 3 mm[5, 9]).

The posterior fossa findings prompted a more detailed search for other abnormalities and revealed a ventricular septal defect (patients 1 and 5), rocker-bottom feet (patients 2 and 4), and cleft lip (patient 2). The constellation of ultrasonographic findings suggested a trisomy syndrome. Chromosome analysis of amniotic fluid or fetal cord blood confirmed the diagnosis in patients 2, 3, 4, and 5. These fetuses were delivered vaginally without monitoring and either were stillborn or died shortly after birth. Patient 1 presented in active labor and was counseled regarding the high likelihood of a lethal chromosomal abnormality in her fetus. However, because fetal distress developed before chromosome analysis could be performed, the fetus was delivered by cesarean section and died 7 days later.

Newborn No. 1 had a postpartum computed tomography scan of the head that revealed cerebellar and vermian hypoplasia with partially fused lateral ventricles. Fetus No. 2 had an autopsy that indicated cerebellar hypoplasia. Fetuses 3, 4, and 5 did not undergo postmortem examination.

Additional findings that were not identified by prenatal ultrasonography were single umbilical artery, short sternum, finger flexions, and left diaphragmatic eventration (fetus No. 1); small placenta and low-set ears (fetus No. 2); clenched fists and low-set ears (fetus No. 3); and hypotelorism, clinodactyly, and low-set ears (fetus No. 4).

Comment

The more common findings in trisomy 18 are quite subtle: polyhydramnios, small placenta, single umbilical artery, growth deficiency, prominent occiput, narrow palatal arch, low-set ears, clenched or overlapping fingers, short sternum, inguinal and umbilical hernias,

Prospective ultrasonographic findings						
Amniotic fluid	*CI (%)*	*Fetal anomalies*	*Cerebellar width (cm)*	*Predicted BPD (cm)*	*Actual BPD (cm)*	*Cisterna magna (cm)*
None	82.8	VSD, hypotelorism	3.2	6.6-7.4	8.0	1.6
Slightly decreased	79.4	IUGR, bilateral hydronephrosis, cleft lip, rocker-bottom foot	3.7	7.3-8.1	8.8	1.7
Increased	85.8	IUGR	4.1	7.8-8.5	8.6	2.3
Increased	81.9	IUGR, rocker-bottom foot, hypotelorism	3.3	6.8-7.5	8.3	2.1
Decreased	81.5	VSD	4.5	8.2-8.9	9.1	1.0

ventricular and atrial septal defects, and patent ductus arteriosus.[1] Cerebellar hypoplasia in trisomy 18 is well described but is thought to occur in <10% of affected persons.[1, 10] Our experience suggests this abnormality may be present more often. A recent study utilizing detailed computed tomography and postmortem morphometric analysis of the cerebellum in nine newborns with trisomy 18 supports this concept.[11] All of the patients had cerebellar hypoplasia as a dominant finding, including three who also had hypoplasia of the posterior cranial fossa. This latter observation may explain our patient No. 5, who had a small cerebellum but only a mildly enlarged cisterna magna.

The importance of a large cisterna magna–small cerebellum for prenatal diagnosis of trisomy 18 has been suggested previously based on examination of two fetuses in the third trimester.[8] However, recent reviews of the ultrasonographic findings in trisomy 18 did not include large cisterna magna or small cerebellum as a finding.[2, 3] Cerebellar hypoplasia in infants with open neural tube defects has been described.[12] The incidence of large cisterna magna–small cerebellum by prenatal ultrasonography in trisomy 18 and in other conditions is not known; therefore the predictive value of a normal or abnormal measurement cannot be determined. In a 1-year period at our institution, all five patients diagnosed with trisomy 18 had a large cisterna magna and small cerebellum.

It is also not known how early this finding is present. In the patient initially evaluated at 20 weeks for confirmation of dates, large cisterna magna–small cerebellum was not visualized. We do not know whether in fact it was not present, or was present but not recognized.

The importance of any ultrasonographic finding relates to its impact on clinical management. Except for the patient who presented in active labor, all patients were spared unnecessary monitoring during labor and cesarean sections for fetal distress. Each patient, including the patient in active labor, benefited from counseling before delivery.

Measurements of the cerebellum and cisterna magna are easily obtained by angling the transducer 15 degrees caudal to the standard axial plane used for determining BPD. It is hoped that determination of these parameters in a large number of patients will reveal the true incidence of large cisterna magna–small cerebellum in trisomy 18 and other conditions. Enhanced attention to this finding may also result in its visualization in the first or second trimesters, leading to even earlier diagnosis of trisomy 18.

Neonatal mortality in normal birth weight babies: Does the level of hospital care make a difference?

Cynthia J. Berg, MD,[a] Charlotte M. Druschel, MD, MPH,[a] Brian J. McCarthy, MD,[a] Michael LaVoie,[b] and R. Louise Floyd, RN, MSN[c]

Atlanta, Georgia

Although neonatal intensive care for low birth weight infants has been extensively studied, few researchers have looked at the impact of the level of care at the delivery hospital for infants weighing >2500 gm. Using linked birth-death records from Georgia for 1979 to 1982, we examined the effect that the level of care available at the hospital of delivery had on neonatal mortality in infants weighing 2500 gm and above. We used a risk scoring system designed for use with vital records to determine prepartum risk and the presence or absence of a complication of labor as indicated on the birth certificate to determine intrapartum risk. We found that women with a high prepartum risk score had increased neonatal mortality at level 1 hospitals. Women who developed a complication of labor, regardless of their prepartum risk status, had the highest neonatal mortality rates when they delivered at level 1 hospitals. We suggest prenatal risk assessment for all women and referral of high risk women to level 2 or 3 hospitals for delivery even at term. (AM J OBSTET GYNECOL 1989;161:86-91.)

Key words: Neonatal mortality, regionalization, high-risk pregnancy, hospital level

One of the 1990 *Objectives for the Nation*[1] is to reduce infant mortality to 9/1000 livebirths. Two thirds of U.S. infant deaths occur during the neonatal period (within the first 28 days of life). Among the more successful intervention strategies developed in an attempt to lower neonatal mortality is the establishment of neonatal intensive care units—special hospital facilities for the care of critically ill newborns.

Because birth weight is the strongest predictor of neonatal mortality, we tend to believe that neonatal deaths occur predominantly in low birth weight infants. However, 93% of all infants born in Georgia from 1979 to 1982 weighed 2500 gm or more, and these non–low birth weight infants contributed 26% of the neonatal deaths in the state in that time period. In the Closing the Gap conference in 1985, sponsored by the Carter Center, researchers from the World Health Organization Collaborating Center in Perinatal Care reported that the United States could, with the use of current technologies, reduce infant mortality by 40%.[2] Of the achievable reduction in neonatal mortality, 95% was among infants weighing ≥2500 gm.

Numerous investigators have looked at the effect of the hospital of birth on neonatal mortality rates in low birth weight and very–low birth weight infants, and have found that care in a neonatal intensive care unit improved the survival of these babies.[3-5] However, few investigators have examined the effect of neonatal care facilities in non–low birth weight infants on a population basis.[6, 7]

We examined the impact that the level of neonatal care available at the hospital of delivery had on neonatal mortality in infants with birth weights of 2500 gm and greater (which, for the sake of convenience, we will refer to as normal birth weight babies[7]). We used the presence of prenatal and intrapartum risk factors to help predict neonatal mortality and assess the appropriate level of care for babies in this birth weight group. We used a population-based data set for the years 1979 to 1982, a time period during which neonatal intensive care was widely available.

Methods

Data for this study were provided by the Office of Vital Records, Georgia Department of Human Resources. All birth certificates of infants born to Georgia residents are entered into a computer data base. Each reported death of an infant under 1 year of age who

was born in Georgia is manually linked to its birth certificate. The birth and infant death data bases are merged, providing linked birth-death records by birth year cohort. Check boxes for complications of pregnancy, complications not related to pregnancy, and complications of labor and delivery, as well as other data from the birth certificate, were used to calculate prepartum and intrapartum risk.

All 315,830 singleton, liveborn infants born to Georgia residents between Jan. 1, 1979, and Dec. 31, 1982, with birth weights 2500 gm and above, made up the study population. Neonatal mortality was defined as deaths of liveborn infants at less than 28 days of age per 1000 livebirths.

To assess maternal prepartum risk, we used a neonatal mortality risk scoring system designed specifically for use in studies using vital record data.[8] This system, developed with discriminant analysis, predicts the risk of neonatal death by using information that is available before the onset of labor and that is on the Georgia birth certificate. Seven variables are weighed and summed, yielding a risk score. Scores have been combined into three risk groups—low, moderate, and high (Table I).

As a measure of risk during the intrapartum period, we used the presence of a complication of labor as recorded on the birth certificate. These complications included abruptio placenta, placenta praevia, prolapsed cord, dystocia, maternal hypotension, chorioamnionitis, and breech presentation.

Table II. Distribution (percent) of births and risk-specific neonatal mortality rates* by prepartum risk status in normal birth weight infants: Georgia, 1979 to 1982

Prepartum risk status	*% of births*	*NMR*
Low	55	1.7
Moderate	34	2.3
High	12	4.1
RR of neonatal death 2.5 (95% CI: 2.1, 3.0) (High- vs low-risk group)

*Per 1000 livebirths.

Hospitals were classified as having level 1, 2, or 3 neonatal care capacity by the Georgia Maternal and Infant Council in accordance with the joint American Academy of Pediatrics/American College of Obstetricians and Gynecologists *Guidelines for Perinatal Care*. Assignment of neonatal care level was based on on-site visits by members of the Maternal and Infant Council under the direction of the each of the five regional perinatal care directors. Level 1 facilities provide care for normal, healthy newborns with the capacity to stabilize sick infants for transport. Level 2 facilities have the capacity for an intermediate level of care of more complicated cases, including the administration of intravenous fluids, continuous positive airway pressure and short-term ventilation, and treatment of pneumothoraces. A level 3 facility contains a neonatal intensive care unit capable of complete care of the high-risk fetus, neonate, and mother, has a full-time neonatologist on staff, and can provide specialized neonatal surgery. Information on maternal or prepartum transfer between hospitals was not available. Thus the term "hospital of delivery" refers to the hospital in which the actual delivery occurred.

Statistical analysis was done by means of the Statistical Analysis System (SAS) software package. Rates were compared with the χ^2 technique. Confidence intervals for relative risks were calculated by the Taylor series method.[9]

Results

Neonatal mortality rate by year. The crude neonatal mortality rate for singleton infants weighing 2500 gm and above born in Georgia was 2.3/1000 livebirths in 1979, 2.4 in 1980, 2.1 in 1981, and 1.8 in 1982, with an overall rate for the 4-year period of 2.1/1000 livebirths.

Prepartum risk score. The distribution of births by prepartum risk score group is shown in Table II. More than half of the women delivering normal birth weight infants fell into the low-risk category, whereas 12%

Table III. Distribution (percent) of births by prepartum risk status and hospital level in normal birth weight infants: Georgia, 1979 to 1982

Prepartum risk status	*Hospital level*			
	1	*2*	*3*	*%*
Low	57	23	20	100
Moderate	56	21	22	100
High	55	19	25	100
Overall	57	22	21	100

Table IV. Neonatal mortality by prepartum risk status and hospital level, normal birth weight infants: Georgia, 1979 to 1982

Prepartum risk status	*Hospital level*			*RR of neonatal death at level 1 vs level 3 hospital (95% CI)*
	1	*2*	*3*	
Low	1.7	1.4	1.8	1.0
Moderate	2.4	2.1	2.1	1.2
High	5.0	3.1	3.1	1.6 (1.1, 2.4)

RR, Relative risk; *CI*, confidence interval.

were classified as high risk. The risk of a neonatal death was 2.5 times greater for a high-risk woman compared with a low-risk woman.

Level of care at hospital of delivery. More than half of the women with normal birth weight infants delivered at level 1 hospitals, regardless of their risk status (Table III). The remainder of the deliveries were almost equally divided between level 2 and 3 hospitals, although slightly more high-risk women delivered at level 3 hospitals than at level 2 hospitals.

The effect of the interaction between the prepartum risk group of women and the level of care at the birth hospital on neonatal mortality is shown in Table IV. For low- and moderate-risk women, there was no statistically significant difference in the neonatal mortality rate at level 1, 2, and 3 hospitals. However, for high-risk women, the risk of having a neonatal death was 1.6 times greater if the infant was delivered at a level 1 hospital, compared with a level 2 or 3 hospital.

Intrapartum complications of labor. Complications of labor were reported more frequently in pregnancies among women in the high prepartum risk group—23.7% of such cases compared with 13.8% of low prepartum-risk women (Table V). The rate of these complications was uniformly elevated, from 1.5- to 1.9-fold, among high-risk women compared with low-risk women in all level hospitals. In addition, we found an increase in the reported frequency of complications of labor among low- and moderate-risk women who delivered at level 2 and 3 hospitals.

The presence of an intrapartum complication increased the neonatal mortality rate in all the prepartum risk groups and at all hospital levels, with the neonatal mortality rate as much as five times greater if a complication of labor was present (Table VI). For women who experienced a complication of labor, the risk of a neonatal death was greatest at a level 1 hospital, whatever the prepartum risk status of the mother. For moderate- and high-risk women with a complication of labor, the risk of a neonatal death was least at a level 3 hospital and highest at a level 1 hospital. For low-risk women with a complication of labor, the risk of a neonatal death was essentially the same at level 2 and 3 hospitals.

To evaluate whether the level of hospital or the size (number of deliveries) of the hospital was the factor responsible for this increased risk of neonatal death in high-risk women delivering at level 1 hospitals, we divided level 1 hospitals into those with 1000 or more deliveries and those with under 1000 deliveries per year. This placed 25% of the level 1 deliveries in the high-volume level 1 hospitals and 75% of the level 1 deliveries in the lower volume level 1 hospitals. We found no difference in the neonatal mortality rates in the high-volume versus lower-volume level 1 hospitals among women with an intrapartum complication of labor, regardless of their prepartum risk status (data available on request).

Comment

With few dissenting voices, the concept of regionalization of perinatal services is well accepted today. Regionalization implies providing a level of care for the fetus, mother, and infant that matches the level of risk of the maternal-fetal unit. Regionalization requires (1) an assessment of risk status and (2) provision of the appropriate level of services to the patients, including referral and transport if necessary. This idea has been better explored and accepted for low birth weight and, especially, very low birth weight deliveries than it has for normal birth weight deliveries. Looking at linked birth-death records from four states for 1978 and 1979, Gortmaker et al.[5] found significantly lower mortality rates in infants weighing 750 to 1500 gm who were delivered at level 3 hospitals. Paneth et al.[4] found similar results in 501 to 2250 gm infants born in New York City between 1976 and 1978. Other studies have shown an increasing percentage of deliveries of very low birth weight infants occurring at level 3 centers in the past 15 years.[10] This increased delivery of low birth weight and especially very low birth weight infants at level 3 centers has been found to be associated with a decrease in birth weight–specific neonatal mortality rates.[4, 10]

However, few investigators have looked at the effect

Table V. Reported intrapartum complications (percent) by prepartum risk status and hospital level in normal birth weight infants: Georgia, 1979 to 1982

Prepartum risk status	*Hospital level*			
	1	*2*	*3*	*Overall*
Low	11.7	16.7	13.8	13.8
Moderate	11.2	15.6	15.2	13.1
High	22.4	26.2	24.7	23.7
RR of intrapartum complication 1.7 (95% CI, 1.7, 1.8) (high- vs low-risk women)				

RR, Relative risk; *CI*, confidence interval.

Table VI. Neonatal mortality by prepartum and intrapartum risk status and hospital level in normal birth weight infants: Georgia, 1979 to 1982

Prepartum risk status	*Intrapartum complication*	*Hospital level*			
		1	*2*	*3*	*Overall*
Low	No	1.1	1.1	1.3	1.1
	Yes	5.4	3.3	3.6	4.4
Moderate	No	1.8	1.7	1.9	1.8
	Yes	5.8	4.5	2.7	4.7
High	No	3.0	1.4	1.9	2.4
	Yes	11.5	7.6	5.6	9.1

of the level of care in normal birth weight infants. In an analysis of regional perinatal mortality in Norway, Bakketeig et al.[11] found lower fetal and early neonatal mortality rates in those areas that had higher levels of perinatal medical services, an effect that was most pronounced in infants weighing >3500 gm. In South Carolina, perinatal mortality rates were lower in a program that required delivery at a level 2 or 3 hospital for all participants.[12]

Our results from Georgia seem to indicate several things. Even among women delivering normal birth weight babies, women with a high prepartum risk score had an increased chance of experiencing a neonatal death. However, this risk was lower if the mother delivered at a hospital having level 2 or 3 neonatal care facilities. When looking at prepartum level of risk alone, we found no difference in the risk-specific neonatal mortality rates for normal birth weight infants born in level 2 versus level 3 hospitals.

Complications during labor, however, can develop in any pregnancy. Women who were high risk before the onset of labor had a risk of developing a complication during labor and delivery that was 70% greater than that of low-risk women. This increase in intrapartum complications in high prepartum risk women was present at all hospital levels. Overall, almost one quarter of all women who were high risk in the prepartum period developed some problem in the intrapartum period.

As would be expected, a complication of labor increased the risk of neonatal death in all the risk groups and at all the hospital levels. The chance of neonatal death was from 1.4 to 5.4 times greater in women with an intrapartum complication compared with women of the same prepartum risk group delivering at the same level of hospital who did not develop a complication of labor.

When we stratified by the presence or absence of an intrapartum complication, we found an interactive effect in the relationship between prepartum level of risk, hospital level of care, and risk of neonatal death. In women *without* a complication of labor, those with low and moderate prepartum risk had a risk of a neonatal death that was essentially the same for all levels of hospital care. However, for high prepartum risk women without a complication of labor, we found a 58% increased risk of a neonatal death if the woman delivered at a level 1 compared with a level 3 hospital.

However, for women *with* an intrapartum complication, we found that within *each* risk group, there was a gradient of decreasing neonatal mortality with increasing level of hospital care. For each risk group, women who developed a complication of labor had the greatest risk of neonatal death if they delivered at a level 1 hospital. This was not a function of the volume of deliveries at the level 1 hospitals but seemed to be a characteristic of the level 1 status of the facility.

Despite the lower risk of neonatal death among women in the high prepartum risk group, as well as all women developing a complication of labor if they delivered at a higher level hospital, there was little evidence of referral of such women to these higher level facilities. In its recent evaluation of the cost and effectiveness of neonatal intensive care in low birth weight infants,[13] the U.S. Office of Technology Assessment found that some very low birth weight infants were not delivered at level 3 hospitals despite the fact that improved outcomes, both in mortality and long-term development, were found with referral to neonatal intensive care units. The Office of Technology Assessment found three main reasons for the lack of use of this technology: (1) most important, a lack of awareness on the part of physicians of the improvement in outcome with delivery at an appropriate level facility; (2) the desire of physicians or lower level hospitals to be viewed as capable of providing a complete range of services, and (3) financial inability of the woman to pay for the high cost of neonatal intensive care.

We suspect that the factors cited by the Office of Technology Assessment may play an even greater role in the lack of referral in the case of normal birth weight

infants. The knowledge that normal birth weight babies can and do suffer excess mortality despite their overall low neonatal mortality rate is not widespread and thus may not be fully appreciated. Thus the advisability of referring a high-risk woman who has reached term is frequently not considered. Because of the public perception that all normal birth weight infants survive, hospitals and physicians may be especially reluctant to refer women near term, feeling that it reflects adversely on their abilities. In addition, the prepartum diagnosis of low birth weight and very low birth weight is relatively straightforward, especially in patients for whom gestational age is known. To assess prepartum risk on the basis of criteria other than birth weight, a formal prepartum risk assessment needs to be performed. Although this concept has been discussed for many years, especially in the public health sector, it is not currently the norm in all obstetric practices. The risk scoring method that we used for this study was designed specifically for use with vital record data. However, many excellent clinically based risk systems are available[14, 15] that can incorporate those factors found in prenatal care and provide the caregiver with a more detailed picture of the woman's risk status.

Because we performed a study using linked vital records, we encountered those limitations common to all studies in which vital records are used. (1) The precision of our risk assessment, diagnosis of complications of labor, and inability to look at maternal and neonatal transport were limited by our data source. However, vital records offer the advantage of large numbers of births and deaths and readily available data. We feel that it is an appropriate first approach to take when looking at an event, such as neonatal death in normal birth weight infants, that occurs at a relatively low rate (2.1/100 livebirths in our population). (2) Information on risk factors and complications of labor were recorded retrospectively, with the possibility of recall bias. However, the risk factors are obtained from the maternal medical record and are prepartum events. Thus neonatal outcome should not bias the calculation of the risk score. (3) The potential for incomplete ascertainment exists whenever vital records are used. Since 1974, Georgia birth certificates have contained check boxes for complications of pregnancy, complications not related to pregnancy, and complications of labor and delivery, a method shown to capture more complications than open-ended items. In 1979 to 1982, 95% of Georgia birth certificates were complete for these complications, which leads us to believe that overall ascertainment is satisfactory. In addition, the fact that there was an increased rate of complications of labor in high-risk women at all hospitals indicates that there was not a substantial difference in reporting at the different levels of hospitals.

On the basis of our findings, we suggest that neonatal mortality in normal birth weight infants might be lowered by performing an appropriate clinical risk assessment on all pregnant women and planning to deliver those women with a high prepartum risk score at a hospital with level 2 or 3 neonatal care facilities. Those women who develop a complication of labor, even at term, should be considered for maternal transport if this can be safely accomplished. For this to occur, perinatal care providers and the public need to be educated about the importance of risk assessment and delivery at an appropriate level facility for all babies, regardless of birth weight. Further research should be conducted to corroborate the findings of this study, which used clinical risk assessment instruments and evaluated the safety of intrapartum transport.

If we are to meet our 1990 objectives for neonatal mortality, obstetricians and public health planners must identify those groups at increased risk of mortality and develop specific intervention strategies targeted at specific groups.[16] To achieve this in this era of emphasis on decreasing medical care costs, it is important to use medical technology and health care resources in the most cost-effective manner while still striving for the lowest mortality rate. This implies that the level of care provided directly corresponds to the risk of experiencing an adverse outcome. Our challenge must be to use our current technology in the most effective manner to improve the outcome for all infants, including the 95% that are not low birth weight.

Postdate fetal surveillance: Is 41 weeks too early?

Denise A. Guidetti, MD, Michael Y. Divon, MD, and Oded Langer, MD
Bronx, New York

During an 18-month period, 293 patients had a nonstress test and ultrasonographic evaluation of amniotic fluid volume twice weekly beginning at 41 weeks' gestation. Patients were admitted for induction of labor for either an abnormal nonstress test result or oligohydramnios. A control population consisted of 59 low-risk patients who were delivered between 39 and 41 weeks' gestation and had antepartum testing within 4 days of delivery. Study patients who were delivered between 41 and 42 weeks' gestation had a significantly increased incidence of abnormal nonstress tests, oligohydramnios, cesarean sections for fetal distress, and admissions to the neonatal intensive care unit compared with control patients. The abnormal fetal testing and adverse perinatal outcome associated with pregnancies over 42 weeks were also found in pregnancies between 41 and 42 weeks' gestation. These data support the concept that postdate fetal testing should begin at 41 weeks of gestation. (AM J OBSTET GYNECOL 1989;161:91-3.)

Key words: Postdate pregnancy, antepartum fetal testing

More than 25 years ago, McClure-Browne[1] showed that perinatal morbidity and mortality are increased after 42 weeks' gestation. Eighty percent of these deaths occurred before or during labor.[2] The presumed pathogenesis of the complications associated with the postdate pregnancy relates to progressive uteroplacental insufficiency. As gestational age advances, uteroplacental insufficiency leads to fetal asphyxia, oligohydramnios, meconium aspiration, decreased subcutaneous tissue, and in severe cases fetal central nervous system damage and death.[3]

In recent years improved outcome has been realized through advances in fetal testing. Electronic fetal monitoring and ultrasonography have helped identify the postdate fetus who would benefit from delivery. As a result, current trends favor selective intervention instead of routine induction. A variety of testing protocols have been designed and usually incorporate some combination of the nonstress test, contraction stress test, biophysical profile, or amniotic fluid volume assessment, either weekly or twice weekly. These testing schemes are usually initiated when the pregnancy had exceeded 42 weeks from the onset of the last menstrual period. However, the changes ascribed to the uteroplacental insufficiency of postdate pregnancies probably represent a continuum that may in fact begin before 42 weeks. Several recent studies suggest that perinatal morbidity and mortality actually begin after 40 weeks' gestation.[4, 5]

The purpose of this study was to assess the value of antepartum fetal testing in the 41- to 42-week period.

Material and methods

The study group consisted of 293 patients who had fetal testing at the Hospital of the Albert Einstein College of Medicine between July 1986 and January 1988. To assure accurate assignment of gestational age, study

Department of Obstetrics and Gynecology, Albert Einstein College of Medicine of Yeshiva University.
Received for publication July 20, 1988; revised December 1, 1988; accepted January 10, 1989.

Table I. Perinatal outcome of control subjects and study patients delivered at 41 to 42 weeks

	Control subjects	*Delivery at 41-42 wk*	*p*
No. of patients	59	139	
Abnormal nonstress test	4	34	<0.01
Oligohydramnios	0	19	<0.02
Cesarean section for fetal distress	1	14	<0.05
Apgar score ≤6 at 5 min	0	0	NS
NICU admissions	0	9	<0.05
Perinatal deaths	0	0	NS

NICU, Neonatal intensive care unit.

Table II. Perinatal outcome of study patients delivered at 41 to 42 weeks and <42 weeks

	Delivery at 41-42 weeks	*Delivery after 42 weeks*	*p*
No. of patients	139	154	
Abnormal nonstress test	34	22	<0.05
Oligohydramnios	19	16	NS
Cesarean section for fetal distress	14	14	NS
Apgar score ≤6 at 5 min	0	1	NS
NICU admissions	9	6	NS
Perinatal deaths	0	0	NS

NICU, Neonatal intensive care unit.

patients were required to meet all of the following criteria: (1) last menstrual period known with certainty, (2) regular menses, (3) first-trimester clinical examination that confirmed dates, and (4) an ultrasonographic examination before 20 weeks' gestation consistent with dates.

These patients had no medical or obstetric problems. Antepartum fetal testing began at 41 weeks' gestation and consisted of a nonstress test and an ultrasonographic evaluation of amniotic fluid volume. The nonstress test was considered abnormal in the presence of recurrent variable-late decelerations or 120 minutes of a nonreactive tracing. Oligohydramnios was defined by ultrasonogram as the largest pocket of amniotic fluid <2 cm in vertical depth. Patients were admitted for labor induction for either an abnormal nonstress test result or oligohydramnios. Patients with normal antepartum fetal testing were followed up twice weekly until spontaneous labor occurred.

The control population consisted of patients who were delivered between 39 and 41 weeks' gestation. This was a group of low-risk patients who were referred for routine testing at term. There were 59 such patients during the study period. These patients had their last antepartum assessment within 4 days of delivery. Patients with an abnormal nonstress test result or oligohydramnios were referred for induction of labor. All others labored spontaneously.

Obstetric and neonatal records were reviewed for study cases and controls. Perinatal outcome was evaluated by the following criteria: cesarean section for fetal distress (scalp pH <7.2 or recurrent severe variable-late decelerations occurring in early labor when a scalp pH was technically not obtainable), Apgar scores of ≤6 at 5 minutes, admissions to the neonatal intensive care unit, and perinatal deaths. Statistical analysis was performed by means of the χ^2 test.

Results

Of the 293 patients in the study group, 139 patients were delivered between 41 and 42 weeks' gestation and 154 were delivered after 42 weeks. Perinatal outcome for controls and study patients between 41 and 42 weeks is shown in Table I. The group of women who were delivered between 41 and 42 weeks had a significantly increased incidence of abnormal nonstress tests, oligohydramnios, cesarean sections for fetal distress, and admissions to the neonatal intensive care unit when compared with the control group who were delivered between 39 and 41 weeks. There was no significant difference in Apgar scores.

When the study group who were delivered between 41 and 42 weeks was compared to the women who were delivered after 42 weeks, there was no significant difference in any of the outcome parameters except abnormal nonstress tests. Surprisingly, there were more abnormal nonstress tests in the 41- to 42-week group than in the over 42-week group. There were no perinatal deaths in any of the groups evaluated.

Comment

The results of this study indicate that the abnormal fetal testing and adverse perinatal outcome associated with pregnancies >42 weeks' gestation are also found in pregnancies between 41 and 42 weeks' gestation.

Recent studies that evaluated intrapartum and neonatal parameters suggest that significant morbidity and mortality exist before the period classically used to define the postdate pregnancy (294 days). Grausz and Heimler[5] found the mean gestational age of neonates with unexpected asphyxia to be 288.8 days. Those infants who died or had neurologic sequelae had a mean gestational age of 291 days. Arias[4] showed that complications related to macrosomia, fetal distress, meconium aspiration, and postmaturity significantly increased from 5.6% at 38 to 40 weeks to 24.7% between 41 and 42 weeks. In a recent review on antepartum testing in the postdate pregnancy, Benedetti and Easterling[6] stated that "the traditional use of 42 weeks, or 294 days, to identify the fetus at risk in postterm pregnancy should be reconsidered."

The purpose of this study was to evaluate the role

of antepartum testing in the 41- to 42-week period. When conservative management of the postdate fetus is elected, antenatal testing is used to identify the fetus that needs to be delivered. Abnormal fetal heart rate patterns and oligohydramnios are well-accepted indicators for intervention in pregnancies over 42 weeks.[6] In our study, both of these indicators were found with increased frequencies in pregnancies between 41 and 42 weeks (Table II). This may be explained in part by the fact that patients with abnormal testing between 41 and 42 weeks were referred for induction and were therefore excluded from the over 42-week group. Twenty-five percent of patients who were delivered between 41 and 42 weeks had abnormal nonstress tests and 14% had oligohydramnios. In contrast, a very low frequency of abnormal tests was found in pregnancies between 39 and 41 weeks.

A presumed cause of the morbidity and mortality associated with postdate pregnancies is progressive uteroplacental insufficiency. It is postulated that when the aging placenta cannot keep pace with the demands of the fetus, both chronic and acute compromise become evident in the form of decreased growth, oligohydramnios, and fetal hypoxia.[2] Additionally, Leveno et al.[7] have shown that fetal distress in postdate patients can be explained by oligohydramnios and cord compression.

Several studies have shown increased perinatal mortality after 42 weeks' gestation.[1, 2, 8, 9] The purpose of antepartum fetal testing is to recognize changes in the fetal-placental unit that occur before the onset of permanent fetal damage. Therefore, it is not surprising that fetal testing would detect pathologic conditions before 42 weeks' gestation. In addition, the exact pathophysiologic features of uteroplacental insufficiency are still unclear.[10]

Morphometric studies have attempted to correlate fetal postmaturity with a wide variety of placental lesions. Other investigators have attempted to explain these changes on the basis of biochemical alterations in the postdate fetus.[2] None have been uniformly successful. Additional studies are needed before the uteroplacental insufficiency associated with postdate pregnancies is clearly understood. However, there is increasing evidence to suggest that these changes do not begin in all pregnancies at precisely 294 days.

In summary, this study supports the concept that the traditional use of 42 weeks to identify the fetus at risk does, in fact, need to be reconsidered. These results indicate that postdate fetal testing should begin at 41 weeks of gestation.

Sarcoma associated with pregnancy

Yutaka Kyodo, MD, Kenji Inatomi, MD, and Tadayuki Abe, MD
Shizuoka, Japan

A case is reported of sarcoma associated with pregnancy in which the patient underwent a cesarean section with myomectomy and was delivered of a living infant. A pathologic examination indicated sarcoma. (AM J OBSTET GYNECOL 1989;161:94-6.)

Key words: Sarcoma, pregnancy

Sarcoma is rarely associated with pregnancy. This case report describes a patient with sarcoma in pregnancy. The pathologic examination revealed well-differentiated leiomyosarcoma. The patient was delivered of a healthy infant.

Case report

A 29-year-old, gravida 0, unmarried woman with her marriage near at hand requested the examination of antibody titer for rubella on December 23, 1982. On B-scan ultrasonography there were unclear small myomatous nuclei in the uterus (Fig. 1). Her medical history was noteworthy in that she had infantile rheumatism at 7 years of age and was hospitalized 3 months. On November 25, 1983, at 8 weeks' gestation, on B-scan ultrasonography a tumor three times as large as an adult thumb was detected on the right anterior side of the uterus (Fig. 1). Blood and biochemical test results were normal.

On May 26, 1984, at 34 weeks' gestation, she had abdominal pain, which was eliminated by analgesics. There seemed to be a partial necrosis in the subserous myoma on B-scan ultrasonography (Fig. 1). On June 20, at 37 weeks' gestation, she underwent a cesarean section with myomectomy because of nonreactivity in a nonstress test and a low estriol level. She was delivered of a living 2640 gm infant with an Apgar score of 9. The placenta was intact and it weighed 700 gm. The membrane was normal. The subserous myoma was the size of a goose egg (80 × 55 mm) and it was soft on the right anterior side of the uterus. There were several holes on the surface of the uterus. Fluid-like pus oozed from the holes. The uterus had several subserous myomas, but they were left as they were. The subserous myoma of goose egg size was diagnosed as well-differentiated leiomyosarcoma (Fig. 2).

On July 6, 1984, she underwent a total abdominal hysterectomy. Bilateral ovaries were intact so they were left alone (Fig. 3). After the surgical procedure she received treatment with Picibanil. α-Fetoprotein, carcinoembryonic antigen, ferritin, and CA 125 levels were normal before and after the two operations. On August 6, pyelitis was diagnosed. Picibanil was stopped, and she was discharged from the hospital August 19. We have closely watched the course of the disease.

Comment

Malignant tumor (i.e., malignant ovarian cyst) in pregnancy is rare; it was reported in 1 of 25,000 pregnancies.[1] Sarcoma associated with pregnancy is rarer than malignant ovarian cyst associated with pregnancy. There are many statistical and pathologic reports with regard to sarcoma, but there are few practical case reports that pertain to sarcoma in pregnancy. The sarcoma destructively invaded neighboring tissue and degeneration and necrosis in the tumor center resulted. Sarcoma is well known for its metastasis in the circulation of the blood. The purpose of this case report is to describe the resistance to sarcoma cells during pregnancy.

When we first saw the patient she was not pregnant but had subserous myoma in the uterine cavity. After she was pregnant the subserous myoma gradually interfered with the developing fetus and was pressed into the anterior segment of the uterus. The sarcoma, which we originally thought to be a subserous myoma, was scattered in the pelvic cavity (Fig. 4).

Why couldn't the sarcoma invade the gestational sac? Why couldn't the sarcoma cell in this case pass through the placenta?

Sarcomas are very destructive. But the fetal membrane was neither damaged nor stained yellow by the sarcoma. It was intact. The gestational sac is made up of three layers: amnion, chorion, and decidua (Fig. 4). Chorion consists of five layers: superficial cells, type IV collagen, type V collagen, type III collagen, and type I collagen. In premature rupture of the membranes, the break in the chorion is thought to be made at the layer of type III collagen by esterase of leukocytes.[2] But it also has been reported that cancer cells with strong metastatic power secrete large amounts of type IV col-

lagenase.[3] The patient's placenta was normal; it had no defect and weighed 700 gm.

Chorion and decidua are part of the endometrium. Decidual cells are said to change the fibroblast cells of endometrium. Fibroblast cells are concerned with fibronectin. It is said that fibronectin "catches" carcinoma cells, which enables both leukocytes and macrophages to "kill" them. Fibronectin has an opsonic function against carcinoma cells. There are fibrinoids in the cellular space of decidual cells. We believe the role of fibrinoids is to bind both villi and decidua on myometrium during pregnancy. Deep in the decidua there is decidual spongiosa, which is tough and has a low response level so sarcoma cells cannot invade the gestational sac.

Amnion, chorion, and decidua provide a strong defense against foreign invaders; however, they have a low tolerance to inner invaders such as destructive mole

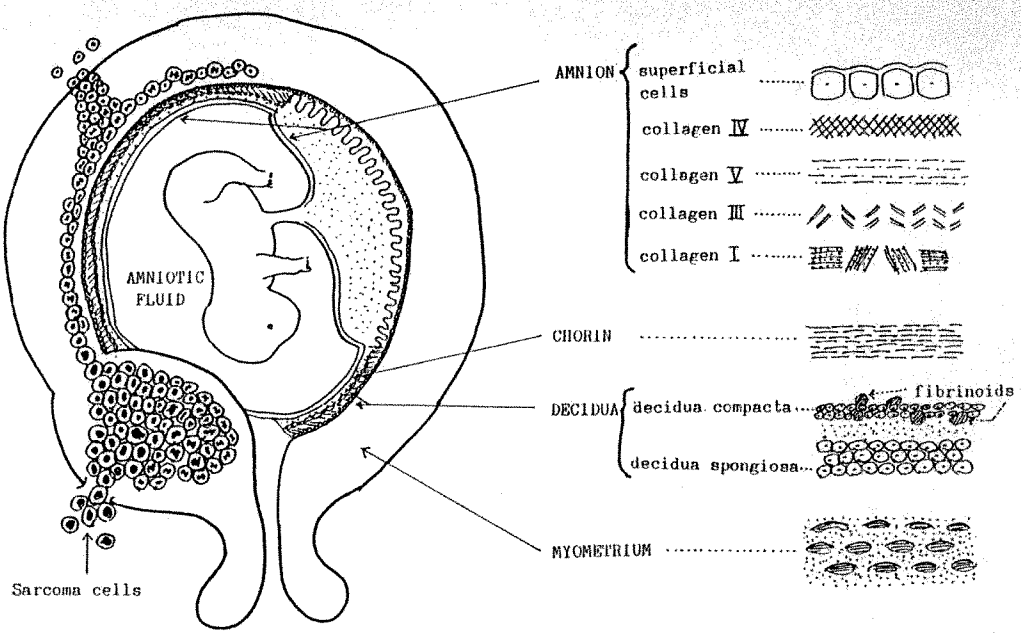

Fig. 4. Sarcoma cells in relationship to structural layers of uterus during pregnancy.

and choriocarcinoma. It is natural for villi to invade the myometrium. The human body is helpless with regard to internal reproductive invaders. From this case it is evident that both homeostasis and a strong instinct to protect the body from the foreign invader exist in the human body.

Primary stress urinary incontinence and pelvic relaxation: Prospective randomized comparison of three different operations

Arieh Bergman, MD, Paul P. Koonings, MD, and Charles A. Ballard, MD
Los Angeles, California

There were 289 women with clinical and urodynamic diagnosis of primary stress urinary incontinence, stable bladder, and pelvic relaxation who underwent a single-stage surgical procedure because of incontinence and pelvic relaxation. Patients underwent one of three surgical procedures because of stress incontinence—anterior colporrhaphy, revised Pereyra procedure, or Burch retropubic urethropexy. Decisions with regard to the type of bladder neck suspension and the surgeon were made randomly with a randomization table. Each patient had a complete clinical and urodynamic evaluation before surgery and at 3 and 12 months after surgery. Cure rate as defined by strict clinical and urodynamic criteria was not significantly different among the three groups at the 3-month postsurgical evaluations; however, at the 12-month postsurgical evaluations, the cure rate among women who underwent Burch urethropexy (n = 101) was significantly higher than that of either Pereyra or anterior colporrhaphy (cure rates were 87%, 70%, and 69%, respectively; $p < 0.01$). The Burch urethropexy was more effective than the Pereyra procedure or anterior colporrhaphy in the stabilization of the bladder base and resulted in a significantly better cure rate in women with primary stress urinary incontinence and pelvic relaxation (Am J Obstet Gynecol 1989;161:97-101.)

Key words: Stress incontinence, pelvic relaxation

Genuine stress urinary incontinence is a pathologic condition usually accompanied by poor support to the pelvic organs and excessive mobility of the bladder base on stress.[1, 2] Anatomically, the pelvic organs are supported by the pelvic diaphragm (levator ani muscle and fascia) and the pubovesicocervical ligaments.[2-4] Failure of support to the bladder frequently is part of a picture of generally defective pelvic support, and pelvic relaxation results in prolapse of both bladder and uterus.[5] Most women with primary stress urinary incontinence and pelvic relaxation will show various degrees of uterine prolapse, cystocele, and rectocele. Surgical procedures to lift and stabilize the bladder and urethrovesical junction frequently necessitate vaginal hysterectomy and posterior colporrhaphy to correct the other components of pelvic relaxation.

Numerous surgical approaches to stabilize the bladder base have been designed. The three most popular surgical approaches for primary stress urinary incontinence are anterior colporrhaphy,[6] vaginal retropubic procedure (Pereyra-Stamey type[4, 7]) and abdominal retropubic procedures (Burch and Marshall Marchetti-Krantz[8, 9]). Comparative studies of the surgical results of these procedures are difficult to interpret because all but one are retrospective studies of various groups of patients with different pathologies and degrees of pelvic relaxation.[10-13] One prospective study was done without author randomization and with the degree of pelvic relaxation uncontrolled.[14] The present work was undertaken to study prospectively and in a randomized comparative manner the results of three different operations for stress urinary incontinence (anterior colporrhaphy, revised Pereyra procedure, and Burch retropubic urethropexy) in women with genuine stress incontinence and pelvic relaxation with the use of objective clinical and urodynamic criteria.

Material and methods

A total of 342 women with clinical and urodynamic diagnosis of primary genuine stress urinary incontinence and pelvic relaxation were evaluated in the Gynecology-Urology Service at Women's Hospital, University of Southern California School of Medicine, between January 1986 and June 1987 and were found to be eligible for this study. Women with previous anti-incontinence surgical procedures or findings of combined stress incontinence with detrusor instability were excluded from the study. Women with gynecologic conditions that required laparotomy were not included. All women had various degrees of pelvic relaxation neces-

‡$p < 0.01$ by χ^2 test compared with Burch procedure.

sitating vaginal correction (cystorectocele repair with or without vaginal hysterectomy). Patients' mean age was 57 years (range, 31 to 80) and mean parity was 3 (range, 1 to 13). There were 191 patients who were postmenopausal and 151 patients who were premenopausal.

Evaluation included history and physical examination with neurologic screening tests of the S_2 to S_4 lower micturition center, urine culture, Q-tip test, dynamic water urethrocystoscopy, standing provocative urethrocystometry (at a filling rate of 60 ml/min), and urethral pressure profiles at rest and stress (repeat coughing) in the sitting position at maximal cystometric capacity. Pressures in the abdomen (approximated by vaginal recording), bladder, and urethra were measured with two small (4 French) catheters with microtip pressure transducers (Models 20K 60 and 20K 62, Dantek Electronics) and recorded on a six-channel electrophysiologic recorder (Model 2100, Dantek Electronics, N.J.). All postmenopausal women received Premarin vaginal cream (1 gram daily) for a minimum of 2 weeks before urodynamic evaluation and 4 additional weeks before surgery. These patients were encouraged to continue estrogen replacement therapy indefinitely.

Nineteen of the 342 women had had a previous hysterectomy because of benign conditions and were scheduled to undergo vaginal cystorectocele correction in addition to the anti-incontinence operation. The other 323 women were scheduled for vaginal hysterectomy and cystorectocele repair in addition to their anti-incontinence procedure. All women in this series had pelvic relaxation that necessitated vaginal surgery. When hysterectomy was not indicated, women with genuine stress incontinence and minimal pelvic relaxation or with a well-supported uterus had an anti-incontinence procedure only and were entered into a different protocol that was reported separately.[15] Vaginal hysterectomy was abandoned because of technical difficulties in three women (two had endometriosis and one had previous pelvic inflammatory disease). These three patients underwent abdominal hysterectomy and were not included in the final analysis.

After clinical and urodynamic evaluation, patients were randomly assigned (with the use of a randomization list[16]) to one of three anti-incontinence surgical procedures. Randomization included the type of anti-incontinence procedure as well as the surgeon (one of the three authors). All surgical procedures were done by house staff and one of the three authors. Results of the urodynamic studies or the severity of stress incontinence were not considered when the type of anti-incontinence operation was selected. Women in group 1 had Burch urethropexy after the vaginal surgery. Women in group 2 had a modified Pereyra procedure after surgery for pelvic relaxation, and women in group 3 had anterior colporrhaphy as their anti-incontinence procedure (in addition to cystocele and rectocele repair with or without vaginal hysterectomy). Anterior colporrhaphy was performed by mobilization of the bladder with upward displacement and buttressing of the bladder neck with the use of Kelly plication sutures, which included the pubocervical fascia with a delayed absorption suture (#0 Vicryl[6]). The modified Pereyra procedure included all of the modifications of the original technique with special emphasis on inclusion of the pubourethral ligaments and endopelvic fascia at the level of the proximal urethera and bladder neck with use of delayed absorbable sutures (#0 Vicryl) under endoscopic guidance.[4] The Burch urethropexy included the basic principles of the Tanagho modification[8]: (1) minimal dissections within 2 cm of the urethrovesical junction and urethra; (2) placement of sutures through the full thickness of the paravaginal fascia; (3) use of two delayed absorbable sutures (#0 Vicryl) on each side, one opposite of the urethrovesical junction and another at the level of the midurethra; (4) removal of fatty tissue lateral to the sutures to stimulate fibrosis; and (5) tying of the sutures to the Coopers ligament with the use of intravaginal fingers to elevate the anterior vaginal wall. After surgery the bladder was drained by suprapubic catheter (5 F Bonnano catheter). The catheter was removed once; postvoid residual volume was $\leq$50 ml on two consecutive occasions.[17]

Clinical and urodynamic evaluations were repeated at 3 months and 12 months after surgery. A total of 339 patients were eligible for this study (342 minus the 3 who started as vaginal hysterectomy patients and became abdominal hysterectomy patients). There were 298 patients available for 1-year follow-up and they are the subject of this report. The other 41 patients were lost to follow-up.

International Continence Society[18] except where specifically mentioned. Cure from stress incontinence is defined as no history of urinary incontinence after surgery, no loss of urine at any postsurgical evaluation, and negative cough profile on postsurgical urodynamic testing. Few women with presurgical findings of a stable bladder had postsurgical cystometric findings of detrusor instability. They were considered to be "cured" if the detrusor instability was only a urodynamic finding with no subjective or objective evidence of urinary incontinence. The two-tailed paired t test and χ^2 tests were used for statistical anaylsis of the results.

Results

Of the 298 women in this study, 101 had Burch retropubic urethropexy as their anti-incontinence procedure (group 1), 98 women had a Pereyra procedure (group 2), and 99 had anterior colporrhaphy as their anti-incontinence procedure (group 3). The three groups were comparable with regard to mean age, parity, and menopausal status. As shown in Table I, the failure rates 3 months after surgery were higher with the Pereyra procedure and anterior colporrhaphy, although this was not statistically significant. At the 1-year postsurgical evaluation, the failure rate of Burch retropubic urethropexy was significantly lower than that of either the Pereyra procedure or anterior colporrhaphy ($p < 0.01$, Table I). The failure rate of the Burch procedure was similar at the 3-month and 12-month postsurgical evaluations, whereas many failures of the other two procedures (Pereyra and anterior colporrhaphy) occurred between the 3-month and 1-year postsurgical evaluations (Table I).

None of the three procedures resulted in significant changes in urethral resting parameters of functional length or closure pressure (Table II). All three procedures resulted in significant increase in abdominal pressure transmission to the urethra with cough only when the procedure was successful (Table II).

Known risk factors such as presurgical low urethral pressure,[19] presurgical negative Q-tip test results,[20] and previous hysterectomies[21] were equally distributed among the three groups. Successful Burch procedures resulted in a well-supported urethrovesical junction at the 1-year postsurgical evaluation, as judged by negative Q-tip test results (Q-tip change of ≤30° on straining). Four of the 12 Burch failures had positive postsurgical Q-tip test results (change of Q-tip angle ≥35° on straining). Of the 69 women cured by a Pereyra procedure, 36 had negative postsurgical Q-tip test results after 1 year, whereas 18 of the 29 procedural failures had positive postsurgical Q-tip test results. Of the 65 women cured by anterior colporrhaphy, 36 had 1-year postsurgical negative Q-tip test results, whereas 29 of the 34 procedural failures had positive postsurgical Q-tip test results.

Table III. Resumption of spontaneous postsurgical voiding in 298 patients with stress urinary incontinence

	Procedure		
	Burch	*Pereyra*	*Anterior colporrhaphy*
Days on catheter	4 ± 2.7	4.4 ± 2.3	4.3 ± 2.5

Values are mean ± SD.

None of the procedures resulted in significant postsurgical voiding difficulties, and most women were able to void spontaneously with adequate (≤50 ml) residual urine volume by the fifth day after surgery (Table III).

Comment

Results of this prospective randomized study with the use of strict clinical and urodynamic criteria demonstrate that Burch retropubic urethropexy resulted in a better 1-year cure rate than either the Pereyra procedure or anterior colporrhaphy in women with primary stress urinary incontinence and pelvic relaxation. At the 3-month postsurgical follow-up evaluations, cure rates of the three procedures were not significantly different; however, at the 1-year postsurgical evaluation the differences in cure rates among the three procedures were significant in this study. The cure rates of the Burch procedure were similar throughout the study period, whereas the vaginal techniques did not hold their early good cure rates over time. Numerous clinical studies have retrospectively compared results of vaginal versus abdominal retropubic surgical approaches for stress urinary incontinence.[10-13] The majority of these retrospective comparative studies demonstrate that long-term results of the vaginal procedures are not as good as the abdominal ones.[11-13] All of these studies have the weakness of being retrospetcive series with different surgical approaches performed on different populations. Stanton et al.[14] compared vaginal versus abdominal retropubic procedures in a prospective manner, but patients and surgeons in that study were not randomized. The results of Stanton's series show that the vaginal operation is not as good as the abdominal retropubic procedure with long-term objective follow-up.[14] The present series confirms the previous retrospective observations as well as Stanton's findings, in a prospective randomized manner.

Only two criteria were used in this study to assess surgical results—"cure" or "failure." No patients were described as "improved" because such a diagnosis leaves room for subjective interpretations and personal bias. More than half of the procedures considered as failures by strict objective criteria were not considered to be failures by subjective criteria of the patients. The differences among subjective and objective criteria were similar in the three groups.

Primary stress urinary incontinence is usually accompanied by various degrees of pelvic relaxation. Pelvic relaxation often requires vaginal correction in addition to anti-incontinence bladder neck suspension. A surgeon who performs a vaginal operation is tempted to do a vaginal bladder neck suspension because the patient is already positioned for vaginal surgery. To change the patient's position to "frog leg" and to redrape her for abdominal incisions adds about 10 minutes to surgical time and requires additional nursing work to reposition the patient. Improved long-term surgical results, as reported in this series, justify this extra time and effort.

The three techniques of bladder neck suspension are those practiced in the community, although they have undergone some modifications. The Pereyra procedure we described has few of the elements of the Stamey bladder neck suspension.[7] Pereyra et al.[4] in their last report used nonabsorbable sutures. We have used delayed absorbable sutures as described earlier,[13] and used similar sutures in all three procedures.

Known risk factors such as preoperative low urethral pressure,[19] negative Q-tip test results,[20] or previous operations[21] were equally distributed among the three groups and did not apparently affect differences in final cure rate. All three procedures increased abdominal pressure transmission to the urethra when successful, and all three procedures had an insignificant effect on urethral closure pressure or urethral functional length. All procedures resulted in adequate resumption of spontaneous postsurgical voiding. The primary difference among the three procedures was their ability to stabilize the bladder base, as evaluated by postsurgical Q-tip test results. The Burch procedure stabilized the bladder base and urethrovesical junction better than did the two vaginal procedures. Many women who were clinically cured of their stress incontinence after their vaginal procedure still had increased bladder base mobility as judged by positive postsurgical Q-tip test results. This finding indicates that other factors may have cured these women other than the stabilization of their bladder base. Women may be continent during stress despite increased bladder base mobility by a kinking effect on the urethra as suggested by Beck[22] and Bump,[23] or by increased abdominal pressure transmission to the urethra through the rectum as suggested by Hertogs and Stanton.[24] The main difference in clinical response among the three groups was in long-term cure rate. Positive postsurgical Q-tip test results and increased bladder base mobility after the vaginal procedures may represent a less effective bladder base support, which may result in further clin-

ical failures. Longer follow-up of 3 to 5 years is necessary to deterimne whether this is true.

Results of this series demonstrate that the Burch retropubic urethropexy was more effective in treating genuine stress incontinence in our study than either the Pereyra procedure or the anterior colporrhaphy. Anterior colporrhaphy and the Pereyra procedures are associated with a 70% objective cure rate, which makes them reasonable options for patients with primary genuine stress urinary incontinence, if a procedure has to be terminated quickly because of a patient's poor general condition, or if the patient refuses abdominal procedure.

Saline solution amnioinfusion for oligohydramnios after premature rupture of the membranes

A preliminary report

Motoharu Imanaka, MD,[a] Sachio Ogita, MD,[a] and Tadashi Sugawa, MD[b]
Osaka, Japan

In the conservative management of premature rupture of the membranes, most patients have oligohydramnios caused by continuous leakage of amniotic fluid. To avoid unfavorable effects of oligohydramnios on fetal development and well-being, we infused physiologic saline solution continuously into the amniotic cavity at a flow rate of 10 to 20 ml/hr with a new cervical indwelling catheter (PROM-fence). As a result the average pocket size of amniotic cavity was 2.7 cm before amnioinfusion, 5.9 cm 1 day after, 5.8 cm 5 days after, and 5.0 cm 10 days after amnioinfusion. The saline solution amnioinfusion made it possible to keep the amniotic cavity fluid level adequate. Variable deceleration disappeared in one case. No side effects such as uterine contractions were observed. We recommend the method of saline solution amnioinfusion for its favorable effects on fetal environment during management of premature rupture of membranes. (Am J Obstet Gynecol 1989;161:102-6.)

Key words: Saline solution amnioinfusion, oligohydramnios, premature rupture of the membranes, cervical indwelling catheter

Premature rupture of the membranes (PROM) is a major cause of preterm delivery. Management of PROM remains one of the most important unsolved obstetric problems. When PROM is managed conservatively, most patients have oligohydramnios to a greater or lesser degree as a result of the continuous leakage of amniotic fluid. Neonates delivered from pregnancies complicated by oligohydramnios sometimes have pulmonary hypoplasia, retarded growth, or both, because physiologic fetal growth, especially fetal lung development, requires a critical volume of amniotic fluid.[1, 2] Theoretically, the absence of amniotic fluid allows the uterus to exert continuous pressure against the fetus, resulting in abnormal fetal growth and development.

Mosberg et al.[3] reported a high rate of cesarean section for fetal distress because of intrapartum fetal heart rate patterns consistent with umbilical cord compression. They speculated that the high incidence (76%) of severe variable deceleration in patients with fetal distress was a result of oligohydramnios.

There are no effective ways to treat oligohydramnios in the conservative management of PROM. Most patients are simply treated with bed rest in Trendelenburg's position.

We devised a new cervical indwelling catheter (PROM-fence) to solve the clinical difficulties associated with PROM. The catheter plugs the rupture and prevents the outflow of amniotic fluid and ascending infection.[4, 5] Even with this technique it is very difficult to restore the amniotic fluid volume, much of which has been lost before the insertion of the catheter. To prevent unfavorable effects on fetal development and health, saline solution containing dissolved antibiotics is infused continuously into the amniotic cavity.

Material and methods

The study group consisted of 10 women between 22 and 32 weeks of gestation with amniotic fluid loss (the pocket size as defined by Manning et al.[6] was <5 cm). After cervical cerclage, a cervical catheter was inserted into the cervix and fixed by inflating its balloons with antiseptic solution. Antiseptic solution sterilized the inside of the cervical canal and the vagina through an opening between the balloons at a flow rate of 20 ml/day.

We also infused saline-containing antibiotics directly into the amniotic cavity through the catheter. The amnioinfusion equipment included intravenous extension tubing, a three-way stopcock, and 500 ml saline solution containing an antibiotic (100 mg of latamoxef sodium). Saline was infused continuously through the extension

tubing and the main duct of the catheter at the rate of 10 to 20 ml/hr until delivery.

During the amnioinfusion the amniotic fluid volume was measured periodically by the method of Manning et al.[6] Uterine contractions were recorded by an external tocodynamometer or by fetal heart rate tracings. The speed of infusion was regulated primarily according to the size of the amniotic cavity.

In 71 pregnant women between 12 and 41 weeks' gestation, amniotic fluid samples were obtained for measurement of the osmotic pressure. The results were compared with patients receiving saline solution amnioinfusion for 1 day.

Results

The mean time when PROM occurred was at 26.4 ± 3.2 weeks of gestation. The mean interval between rupture and insertion of the catheter was 2.6 days. Labor occurred or was induced 8.3 days after insertion; the mean birth weight was 1084 gm. The reasons for delivery were pulmonary maturation in six cases, and uterine contraction in four. Three of 10 deliveries (30%) resulted in perinatal death. Causes of death included multiple anomalies (one case), spontaneous abortion at 23 weeks of gestation in one case, and pulmonary hypoplasia in one (Table I). Two infants had mild respiratory distress syndrome. Seven infants, in-

cluding the two with respiratory distress syndrome, developed normally with no clinical difficulties such as infection, electrolyte disorders, or jaundice.

Fig. 1 is an echogram of a patient with PROM taken at 25 weeks' gestation. Before insertion of the catheter, the pocket size was 2.4 cm and the cervix was dilated to 2.5 cm. After insertion, saline solution was infused at a rate of 10 ml/hr. The pocket size increased to 5.1 cm after infusion of 150 ml and to 6.0 cm after infusion of 300 ml and was kept at an adequate level thereafter. In this case, 6 days after catheter insertion, uterine contractions increased and the cervix dilated gradually. The catheter slipped out and amniotic fluid leaked freely. The pocket size decreased to 3.4 cm 12 hours later and to 2.1 cm 4 days later.

The average pocket size in those patients with PROM was 2.7 ± 0.9 cm before amnioinfusion, 5.9 ± 0.8 cm 1 day after, 5.8 ± 1.4 cm 5 days after, and 5.0 ± 1.6 cm 10 days after amnioinfusion (Fig. 2). Saline solution amnioinfusion had no effect on the fetal heart rate. Variable decelerations disappeared with enlargement of the amniotic cavity in one case (Fig. 3).

Amnioinfusion had little effect on uterine contractions (Table II). A patient with uterine contractions every 10 minutes or less was considered a positive contraction case. Of seven patients without uterine contractions before insertion, four were having positive contractions 3 hours after amnioinfusion, but by 12 hours after the insertion none had contractions.

Osmotic pressure gradually decreased as pregnancy progressed (269.2 ± 7.1 mOsm/kg before the twenty-third week, 261.2 ± 9.0 mOsm/kg between the twenty-fourth week and the thirty-fifth week, and 253.6 ± 9.9 mOsm/kg after the thirty-sixth week). Conversely, osmotic pressure after saline solution amnioinfusion was 273.7 ± 5.2 mOsm/kg, slightly higher than that of normal amniotic fluid (Fig. 4).

Comment

Oligohydramnios with PROM may cause fetal pulmonary hypoplasia, fetal distress, and is thought to be an uncomfortable environment for the fetus.

If a conservative approach to the management of PROM is taken and a prolonged latency period occurs, the suspected association between oligohydramnios and pulmonary hypoplasia becomes increasingly important. The greatest impact of prolonged membrane rupture on fetal development occurred in patients in whom membranes ruptured before 26 weeks' gestation and the duration of leakage was more than 5 weeks.[1]

Normal fetal lung development during pregnancy requires a critical volume of amniotic fluid. It is important to keep the amniotic cavity large enough for a fetus to breathe and move freely. Nakayama et al.[7] showed that the compressive effects of oligohydramnios inhibit normal fetal body and lung growth and that maintaining the amniotic cavity by saline solution amnioinfusion can prevent fetal pulmonary hypoplasia in rabbits.

Moreover, oligohydramnios resulting in cord or placental compression or both is probably the most common cause of variable decelerations. When variable decelerations occur after PROM, it is reasonable to enlarge the amniotic cavity to release cord or placental

compression. Miyazaki and Nevarez[8] performed intrauterine saline solution amnioinfusion in 49 patients when fetal repetitive variable decelerations did not respond to conventional therapy, such as maternal position changes and oxygen administration. Saline solution amnioinfusion effectively stopped repetitive variable decelerations in 25 of the 49 patients (51.0%); in the noninfusion group decelerations stopped in only 4.2% of patients.

Nageotte et al.[9] reported that prophylactic intrapartum amnioinfusion has significant benefit in reduction of the incidence of variable decelerations and improving the metabolic state in newborn infants born to women with PROM. This was supported by the fact that variable decelerations disappeared after saline amnioinfusion in our study.

However, their method cannot always be applied in the conservative management of PROM because it is difficult to keep the amniotic fluid volume adequate only by infusion of saline solution. Prevention of leakage of amniotic fluid with the catheter must accompany amnioinfusion of saline solution.

The volume of saline solution infused must be appropriate for the length of gestation and the degree of oligohydramnios. Saline solution was usually infused at a rate of 10 or 20 ml/hr. Because the rupture is not completely sealed, excess fluid flows out through the gap. The amniotic cavity can be maintained in its physiologic state of 5 to 8 cm of pocket size without excess enlargement. No effect on uterine contractions was observed at the flow rate we used.

The antibiotic in the saline solution used for amnioinfusion spreads so completely through the amniotic fluid that the level is high enough to inhibit bacterial growth in the amnion and the fetal skin, eyes, ears, genitalia, respiratory tract, and gastrointestinal tract without any significant systemic absorption of antibiotics.[10] In this study, 200 μg/ml of latamoxef sodium in the saline solution was considered adequate to destroy sensitive microorganisms in the uterine cavity.

Insertion of the catheter and saline solution amnioinfusion are thought to induce uterine contractions, but uterine contractions in all our cases were not strong and could be controlled. Amnioinfusion has no effect on uterine contractions; no patients had intrauterine pressure >10 mm Hg. The duration of time patients were managed with the saline solution amnioinfusion catheter was 8.3 days, which was not significantly different from patients treated with the catheter alone.

One infant died of pulmonary hypoplasia despite enlargement of the amniotic cavity. The time of the rupture was not known, and oligohydramnios had continued for over 2 weeks before saline solution amnioinfusion was started. There were two other perinatal deaths. If two cases (one malformation case and one abortion case) were excluded, however, the death rate was 12.5%. No deaths caused by infection or respiratory distress syndrome were observed. Seven infants developed normally.

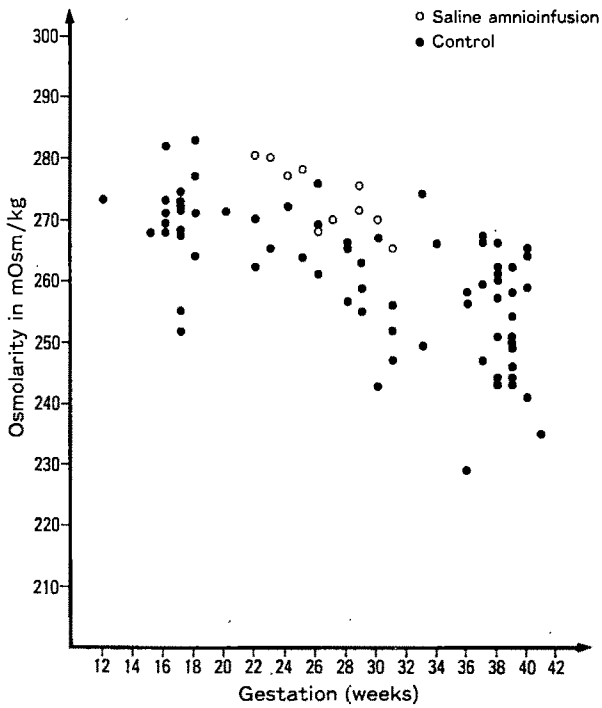

Fig. 4. Effect of saline solution amnioinfusion on osmotic pressure.

We used saline solution, which is as isotonic as serum, for the infusion fluid. Saline solution is considered suitable to prevent compression of the umbilical cord and pulmonary hypoplasia. However, physiologic saline solution is higher in osmolarity than natural amniotic fluid, and osmolarity after saline solution amnioinfusion increased slightly but was kept at most normal levels. Amniotic fluid samples could not be obtained before amnioinfusion for oligohydramnios; thus comparison of osmolarity of amniotic fluid before and after amnioinfusion could not be made. However, amniotic fluid contains various substances and plays an important role in fetal nutrition. Therefore fluid that contained various amino acids and electrolytes was deemed a better infusion solution.

The purpose of saline solution amnioinfusion is to maintain the physiologic intraamniotic environment, which is possible with the use of our cervical catheter. The method of saline solution amnioinfusion is recommended for its favorable effects on fetal environment during the management of PROM, although the cases in this preliminary study were limited.

Prematurity among insulin-requiring diabetic gravid women

Michael F. Greene, MD,[a,b] John W. Hare, MD,[b] Martha Krache, RN, MPH,[a] Mark Phillippe, MD, Vanessa A. Barss, MD,[a] Daniel H. Saltzman, MD,[a] Allan Nadel, MD, [a] M. Donna Younger, MD,[b] Linda Heffner, MD, PhD,[a] and J. Elizabeth Scherl, MD[a]

Boston, Massachusetts

From Jan. 1, 1983, through Dec. 31, 1987, 420 gravidas with insulin-requiring diabetes antedating pregnancy delivered on the Joslin Clinic service. Among them, 110 pregnancies (26.2% of the total) delivered before 37 completed weeks of gestation compared with a 9.7% incidence (906/9368) for the general population at the Brigham and Women's Hospital during calendar year 1985. Thirty-three percent of all premature deliveries were the result of the development of preeclampsia. The relative risk of prematurity for diabetic patients with any hypertensive complication was 2.0 (95% confidence interval, 1.40 to 2.87) compared with normotensive diabetic subjects. Compared with the general population, most of the excess risk of prematurity was confined to hypertensive diabetics and normotensive patients of more advanced White class. A history of having had a previous premature delivery, increasing duration of diabetes antedating pregnancy, and carrying a male fetus in the index pregnancy were significantly associated with premature delivery. Future efforts to reduce the incidence of prematurity among diabetic gravidas should be directed toward reducing the incidence of preeclampsia. (AM J OBSTET GYNECOL 1989;161:106-11.)

Key words: Diabetes, pregnancy, prematurity, hypertension

Diabetes mellitus has always been recognized as a serious complication in pregnancy. Twenty years after the introduction of insulin, Lawrence and Oakley[1] published their results from King's College Hospital and reviewed the existing literature. In summarizing the previously reported series, it was striking that although the maternal mortality rate had fallen to 2% to 5% after the introduction of insulin, the perinatal mortality rate of approximately 40% had not changed. Over the next 20 years, maternal mortality was eliminated as a significant problem, and the perinatal mortality rate was halved to approximately 18%. The sources of that mortality remained ketoacidosis, congenital anomalies, late intrauterine death, and prematurity. Ketoacidosis during pregnancy has become a distinctly unusual problem with regular medical care. Current methods of ante-

natal surveillance have reduced the incidence of late intrauterine death to probably less than 1%.[2] Congenital anomalies remain a problem, but efforts at rigorous metabolic control offer the hope that these can be reduced.[3] Although recent advances in neonatal care have substantially reduced the morbidity and mortality associated with prematurity, it still remains the most important determinant of neonatal morbidity in diabetic pregnancy.[4] Prematurity and its sources in a diabetic population have not been systematically addressed in recent years.

Before the advent of contemporary methods for antepartum monitoring, prematurity among infants of diabetic mothers was commonly iatrogenic in an effort to avoid late death. Although this source of prematurity has been largely eliminated, the incidence of prematurity among infants of diabetic mothers remains high. Some recent reports have dealt with various aspects of prematurity among infants of diabetic mothers. Miodovnik et al.[5] reported a very high incidence of premature labor but did not mention the incidence of premature delivery resulting from that preterm labor. In a series reported by Zalut et al.[6] the incidence of both premature labor and resultant premature delivery was lower than that for a control nondiabetic population. Diamond et al.[7] examined the role of hypertension in prematurity among infants of diabetic mothers and concluded that it was not a significant problem. In a literature review of reported series, Cousins[8] examined the incidence of various complications among diabetic gravidas. Some of the complications that he tabulated could result in premature delivery, but prematurity was not the focus of his study. This report details the incidence, sources of, and some risk factors for prematurity in a large series of patients with insulin-requiring diabetes antedating their pregnancies.

Patients and methods

Data on all patients presenting for prenatal care at the Joslin Clinic prenatal clinic are recorded in a computer-based perinatal data base at the initial visit. Subsequently, data pertaining to the progress of their pregnancies are collected prospectively. Delivery data are obtained by review of the patients' charts within 24 hours of delivery. Data are accumulated on the postpartum course and neonate prospectively, and all mother and infant charts are finally reviewed after discharge.

This series includes all patients with insulin-requiring diabetes antedating pregnancy (White Classes B and greater) delivering between Jan. 1, 1983, and Dec. 31, 1987, at greater than 20 weeks' gestation. No patients with gestational insulin-requiring diabetes are included. Patients were classified according to the system of White as modified by Hare and White.[9] For purposes of these analyses, 16 patients with nephropathy (Class F), 39 patients with nephropathy and retinopathy (Class FR) and four patients with renal transplants (Class T) are grouped together as Class F.

As a matter of policy, insulin-requiring diabetic patients were generally delivered between 38 and 39 weeks. Nonstress tests were performed weekly from 32 weeks and twice weekly from 36 weeks until delivery. Patients delivering before 37 completed weeks were considered to have delivered prematurely. Gestational ages were determined by the best available criteria, last menstrual period, basal body temperature chart, or first-trimester ultrasound examination. For each premature delivery, the immediate cause for premature delivery was determined. Cases of premature labor with spontaneous rupture of the membranes were assigned to spontaneous rupture of the membranes as the cause of prematurity. All cases of preeclampsia met the standard criteria of blood pressure in excess of 140/90 on at least two occasions separated by 6 hours and proteinuria in excess of 300 mg per 24-hour period. Some patients had apparently simple preeclampsia, whereas others clearly had preeclampsia superimposed on chronic hypertension. Any patient with blood pressure measurements in excess of 140/90 on at least two occasions separated by at least 6 hours was considered to have hypertension.

Data regarding the gestational ages at the time of delivery for all the hospital's deliveries were accumulated in a separate data base. Gestational ages were assigned after reviewing the data provided for each patient by each attending obstetrician.

Statistical methods used included χ^2 analysis, the Mantel-Haenszel χ, and the stratified, weighted Mantel-Haenszel χ according to the technique of Rothman.[10] A probability of <0.05 was taken to be statistically significant.

Results

There were 413 singleton, six twin, and one triplet gestations delivered during the study period. Among them 110 pregnancies were delivered before 37 completed weeks (26.2% of the total). These included six of the seven multiple gestations. Two of the multiple gestations were delivered due to preeclampsia, two due to evidence of fetal distress, and one each due to spontaneous rupture of the membranes and abruptio placentae. The premature deliveries are listed in Table I according to the cause of the premature delivery. The four singleton intrauterine deaths occurred as follows: (1) at 22 weeks in a patient with severe chronic hypertension; (2) at 30½ weeks with chorioamnionitis and sepsis after amniocentesis in a patient with severe preeclampsia; (3) at 33½ weeks in a chronic alcoholic with acute pancreatitis, adult respiratory distress syndrome,

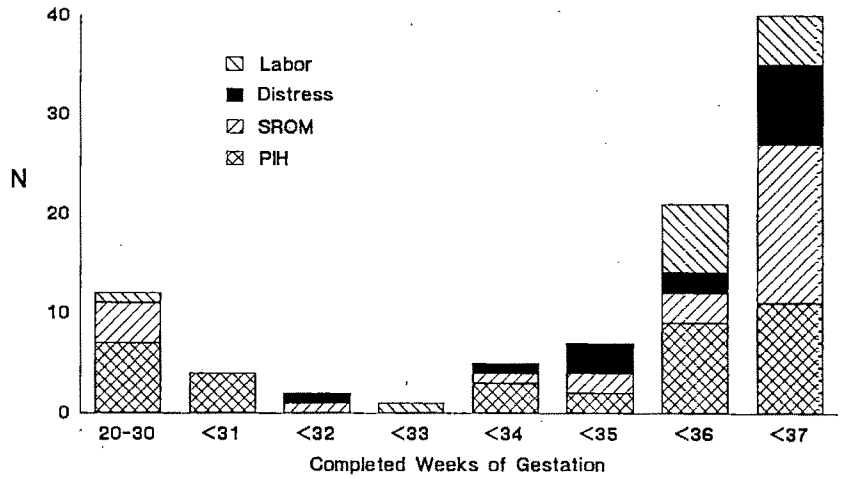

Fig. 1. Premature deliveries displayed according to gestational age and cause for four leading causes of prematurity. *Labor,* Premature labor; *Distress,* fetal distress; *SROM,* spontaneous rupture of membranes; *PIH,* preeclampsia.

Table I. Deliveries between 20 and 37 weeks of gestation by indication for delivery

	N	%
Preeclampsia	36	8.6
Spontaneous rupture of membranes	27	6.4
Fetal distress	15	3.6
Spontaneous onset of labor	14	3.3
Hemorrhage, abruptio, or previa	5	1.2
Intrauterine death	4	0.9
Polyhydramnios' maternal discomfort	4	0.9
Other	5	1.2
Total	110	26.2

acute renal failure, disseminated intravascular coagulopathy, and diabetic ketoacidosis; and (4) at 35 weeks in a patient with poor glycemic control but an otherwise unremarkable pregnancy. A fifth death occurred in a discordant small twin at 33½ weeks. The survivor had mature pulmonary indexes and was delivered for presumed fetal distress. The five patients listed as "other" included the following: (1) an induced abortion at 22 weeks for bilateral renal agenesis; (2) a spontaneous rupture of the uterus at 34½ weeks with fetal salvage in a patient with four prior cesarean sections; (3) a patient with "nephrogenic" diabetes insipidus at 35 weeks; (4) a patient with preeclampsia who had a grand mal seizure in association with a blood glucose level of 22 mg/dl at 35½ weeks; and (5) a patient with an intractable headache at 36 weeks.

The deliveries occurring between 20 and 37 weeks as a result of the four leading causes of prematurity are displayed graphically in Fig. 1. Clearly, preeclampsia is the single most important cause of prematurity in this population. Only 23 (5.5%) of the patients had hypertension antedating pregnancy, but these represent 18.4% of all patients with hypertensive disorders in pregnancy. Among these, 13 were delivered before 37 weeks, with nine the direct result of preeclampsia superimposed on their chronic hypertension. Thus of the 36 premature deliveries directly attributable to preeclampsia, one fourth were superimposed on chronic hypertension.

Although 23 patients were diagnosed as having premature labor with intact membranes and treated with tocolytic agents in this series, only 17 were actually delivered prematurely. Another 10 patients had premature labor with rupture of the membranes (all of whom delivered prematurely), for an overall incidence of premature labor of 7.8% (33/420). Polyhydramnios is difficult to quantitate and is most commonly diagnosed as a clinical impression from physical or ultrasonic examination. The extent to which it contributed to cases of preterm rupture of the membranes or labor is speculative. There were four cases in the 5 years of macrosomia (3500, 4200, 4700, and 5100 gm) associated with severe polyhydramnios, which led to significant maternal discomfort. In these cases amniocenteses at 35, 35½, 36, and 36½ weeks showed mature pulmonary indexes, and these patients were electively delivered before 37 weeks.

The distribution of the premature deliveries among the White Classes is shown in Table II. That this distribution is not random among the classes is demonstrated by a χ^2 analysis that is significant at less than the 0.005 level. The distributions of hypertensive complications and premature deliveries caused by preeclampsia are also shown in Table II. These risks parallel the risk of prematurity in aggregate and are also nonrandom by χ^2 analysis at the 0.005 level. Comparison of the risk of prematurity between hypertensive and normotensive diabetic patients via the Mantel-Haenszel χ

Table II. Prematurity, hypertensive complications, and prematurity caused by preeclampsia by White Class

Class	*No. of premature deliveries (%)*	*No. of hypertensive complications (%)*	*No. of premature deliveries due to preeclampsia*	*Total No.*
B	21 (20.4)	18 (17.5)	5	103
C	21 (17.4)	28 (23.1)	6	121
D	26 (25.7)	31 (30.7)	7	101
F	31 (52.2)	39 (66.1)	14	59
R	11 (30.5)	9 (25.0)	4	36
Total	110 (26.2)	125 (29.8)	36	420

test shows that the risk ratio is statistically significant at 2.00, with a 95% confidence interval of 1.40 to 2.87.

During calendar year 1985, there were 9368 deliveries at the hospital, of which 906 (9.7%) were before 37 completed weeks of gestation. The risk ratios for premature delivery for various groups of diabetics compared with the entire hospital population are shown in Table III. The entire diabetic population as a whole is considerably more likely to deliver prematurely than the general population. Virtually all subgroups of the diabetic population with the possible exception of normotensive White Class B and C patients are significantly more likely to deliver prematurely. Not surprisingly, the greatest risks for prematurity are found among patients with microvascular disease and a hypertensive complication.

No relationship was found between the risk of prematurity and the number of previous pregnancies, the number of previous term births, the number of living children, a history of previous perinatal mortality, or a history of one or more spontaneous or induced abortions. A history of having had a previous premature delivery was significantly associated with premature delivery in the current pregnancy (relative risk 1.60; 95% confidence interval, 1.02 to 2.50). Carrying a male fetus in the current pregnancy was also associated with an increased risk of prematurity (relative risk 1.43; 95% confidence interval, 1.02 to 2.02). Analyses of each of the individual causes of prematurity failed to reveal any one that in itself increased in pregnancies with male fetuses. There was no relationship between maternal age and prematurity. The number of years of diabetes antedating pregnancy was related to the risk of prematurity. Women with 20 or more years of diabetes antedating pregnancy ($N = 70$) were twice as likely to deliver prematurely as women with 19 or fewer years of diabetes (relative risk = 2.0; 95% confidence internal, 1.40 to 2.87).

Table III. Risk ratio for prematurity compared with all Brigham and Women's Hospital deliveries

	Relative risk	*95% Confidence interval*
All diabetics	3.22	2.76-3.75
Normotensive diabetics		
All classes	2.08	1.64-2.64
B	1.70	1.04-2.79
C	1.22	0.7 -2.15
D	2.51	1.62-3.90
F	3.10	1.50-6.39
R	2.68	1.36-5.28
Hypertensive diabetics		
All classes	5.19	4.31-6.25

C	3.69	2.13-6.41
D	3.00	1.66-5.43
F	6.63	4.78-9.18
R	4.59	1.97-10.73

Comment

This report is unique in recording the incidence and sources of prematurity in more than 400 insulin-requiring diabetic pregnancies from a single institution over only 5 years. Other reports of large numbers of pregnancies have either been accumulated over longer periods of time or from a large number of institutions. Furthermore, since all of the pregnancies in this cohort were managed by us, this series represents an unusual degree of homogeneity of care.

Despite the improvements that have been made in the care of diabetic pregnant patients, they remain at increased risk of premature delivery. If this risk is to be reduced by addressing its sources, then those sources must be identified. It is clear from the present series that hypertension or preeclampsia is a common problem among these patients. More than one fourth of the patients had a clinically significant hypertensive disorder. One third of all of the premature deliveries were the result of preeclampsia. Of all patients with a hypertensive complication, 29% had a premature delivery. The incidence of hypertensive complications in this series is quite high. It is higher than that reported by Kitzmiller et al.[11] but very similar to that reported for a comparable population by Gabbe et al.[12] In his 20-year compilation of data from the literature, Cousins[8] found a 14.5% incidence of total hypertension among Classes B and C and a 30.9% incidence for Classes D, F, and R. These figures compare with 20.5% among

Class B and C patients in this series and 40.3% among Class D, F, and R patients.

A recent study[7] called attention to the fact that the issues of perinatal morbidity and mortality related to hypertensive complications in diabetic pregnancy had not been addressed in the context of contemporary perinatal medicine. That study examined 199 insulin-dependent diabetic pregnancies occurring over 7 years at one institution. The authors concluded that hypertensive complications were not a source for major concern with modern management. However, examination of their data shows that there were only 59 hypertensive patients and 33 patients in White Classes D, F, and R. The data from the present study indicate that it is largely hypertensive patients and those normotensive patients in White Classes D, F, and R who are at significant risk for prematurity and hence the morbidity associated with prematurity. Furthermore, the small number of patients in the more advanced classes indicates that there were relatively few patients with diabetes of long duration, which is another important risk factor for prematurity. Since the number of patients at risk in their series was small, their conclusion should not be accepted without reservation.

Urinary albumin excretion increases during both normal pregnancies[13] and those complicated by diabetic nephropathy.[14] It was common among patients in this series to find clinically significant proteinuria develop early in pregnancy in patients with long-standing diabetes but not previously known to have renal involvement. Frequently these patients also developed modest but significant elevations in blood pressure near term. It is unclear whether this truly represents preeclampsia. The designation of preeclampsia in Class F patients who start pregnancy with hypertension and proteinuria is completely arbitrary.

Two recently published, randomized, controlled trials of antiplatelet therapy in high-risk nondiabetic pregnant subjects have shown a decreased incidence of preeclampsia among treated subjects.[15, 16] Neither trial was large enough to convincingly demonstrate a significant reduction in the incidence of prematurity. A diabetic population such as the present one would seem to be an excellent group to study the efficacy of antiplatelet therapy. If it proved efficacious in reducing the incidence of prematurity, it could be a valuable addition to the care of these patients.

The incidence of premature labor with or without rupture of the membranes was 7.8% in this series. This is dramatically different from the 29.9% rate recently found in another series.[5] It would be interesting to know what was the incidence of actual preterm delivery caused by that preterm labor. In this series only 6.4% (27/420) of the patients delivered prematurely in association with premature labor with or without premature rupture of the membranes. The low incidence of premature labor and the high percentage of those diagnosed who then deliver prematurely (82%; 27/33) are probably the result of the strict criteria used to diagnose premature labor. For any group of patients, the more stringent the diagnostic criteria for premature labor, the lower the frequency will appear to be and the lower the number of false-positive diagnoses will be. The hyperglycemia that results from β-agonist tocolytic therapy in diabetic patients makes us reluctant to diagnose premature labor with intact membranes without a clear change in the cervical examination. For these reasons, no conclusions should be drawn from these data with respect to the relative frequency of premature labor or efficacy of its therapy compared with a nondiabetic population.

These findings with respect to risk of premature delivery and past obstetric history are in accordance with those reported elsewhere in a general obstetric population. The relationship between carrying a male fetus and prematurity has also been previously noted.[17] More male than female infants were delivered prematurely in each of the four leading categories of causes of prematurity. However, this effect was modest enough that when broken down into such small data cells, no statistical significance could be found for any one. Interestingly, all four women requiring premature delivery for severe polyhydramnios carried male fetuses. The physiologic mechanisms underlying this sex difference remains a matter of speculation.

The continued prognostic use of the White classification has occasionally been questioned. However, it is clear from this analysis that patients with known nephropathy or long-standing disease and probable subclinical nephropathy have a significantly greater risk of developing a hypertensive complication in pregnancy and a higher likelihood of delivering prematurely as a result. Thus White's classification is useful clinically for an individual patient to alert the physician to the possibility of hypertensive complications. It is also useful in characterizing a patient population because the incidence of prematurity to be expected in that population will depend on the distribution of patients among White's classes.

Management of the nonvertex second twin: Primary cesarean section, external version, or primary breech extraction

Stephen E. Gocke, MD,[a] Michael P. Nageotte, MD,[b] Thomas Garite, MD,[b] Craig V. Towers, MD,[b] and Wendy Dorcester, PhD[b]

Fresno and Long Beach, California

Six hundred eighty-two consecutive twin deliveries were reviewed. Included in the study were 136 sets of vertex-nonvertex twins with birth weights >1500 gm. A primary attempt at delivery of the second twin by external version was performed on 41 twins, 55 twins underwent attempted breech extraction, and 40 patients had a primary cesarean section solely because of physician preference. There were no differences in the incidence of neonatal morbidity or mortality among the modes of delivery. External version was associated with a higher failure rate than primary breech extraction ($p < 0.01$). External version was associated with complications (fetal distress, cord prolapse, and compound presentation) that were not seen in the other two groups. Primary breech extraction of the second nonvertex twin weighing >1500 gm appears to be a reasonable alternative to either cesarean section or external version. (AM J OBSTET GYNECOL 1989;161:111-4.)

Key words: Second twin, cesarean section, external version, breech extraction

The optimal mode of delivery of the nonvertex second twin remains controversial. Certain reports have advocated cesarean delivery if the second twin is nonvertex, suggesting increased perinatal morbidity and mortality in nonvertex twins delivered vaginally.[1-4] More recent reports have suggested that vaginal delivery by breech extraction or assisted breech delivery of the second nonvertex twin is not associated with an increase in perinatal morbidity if limited to infants with birth weights >1500 gm.[5-8] Chervenak et al.[9] advocated the alternative approach of external version of the second nonvertex twin to achieve delivery of the second twin as a vertex presentation. In an effort to examine this controversy we report a comparison of maternal and neonatal outcomes in the second nonvertex twin delivered by cesarean section, external version, or breech extraction for our institutions.

Endometritis	2 (5%)	3 (5%)	1 (2%)	NS

sets of vertex-nonvertex twins with birth weights >1500 gm were eligible for the study. Sixty-six sets of vertex-nonvertex twins who were delivered by cesarean section for failure to progress ($n = 9$), fetal distress ($n = 17$), repeat cesarean section ($n = 28$), cord prolapse ($n = 3$), or other intrapartum complications ($n = 9$) were excluded. The remaining 136 sets of twins (96 sets from Long Beach Memorial Hospital and 40 sets from Valley Medical Center of Fresno) were divided into three groups. Group A ($n = 41$) underwent a primary attempt at delivery of the second twin by external version. Group B ($n = 55$) had a primary attempt at breech extraction. Group C ($n = 40$) consisted of patients in whom a primary cesarean section was performed solely because of physician's preference because of the presence of a nonvertex second twin.

External version was performed according to the guidelines suggested by Chervenak et al.[9] Epidural anesthesia was used in most cases to facilitate abdominal wall relaxation. All versions were attempted under double set-up conditions with immediate access to cesarean section. Real-time ultrasonography was used in every case in the delivery room to determine fetal presentation of the second twin. Fetal heart rate was monitored throughout labor and delivery. Version was accomplished either by using the transducer to guide the infant into vertex presentation in the birth canal or by manually attempting either a forward or backward roll of the fetal vertex into the pelvic inlet. After successful version, membranes were often ruptured and pitocin augmentation was employed to facilitate descent of the vertex.

Breech extraction was performed under double set-up conditions in which immediate access to cesarean section was available. Epidural or halothane anesthesia was used to provide abdominal and uterine wall relaxation. In most cases, real-time ultrasonography was available for determination of fetal lie. The breech extractions were either "assisted," with spontaneous delivery of the breech, or "total," with the entire body of the infant delivered by the obstetrician.

The following maternal variables were considered: maternal age, parity, estimated gestational age, postpartum length of hospital stay, postpartum hemorrhage, and endometritis. Postpartum hemorrhage was defined as any blood loss that required a transfusion. Endometritis was defined as two temperature readings >38° C exclusive of the first 24 hours after delivery and findings on examination of a tender uterus, purulent cervical discharge, or both. The following neonatal variables were compared: birth weights of the first and second twins, Apgar scores at 1 and 5 minutes, incidence of neonatal intensive care unit admissions, respiratory distress syndrome, intraventricular hemorrhage, neonatal deaths, birth trauma, length of infant hospital stay, and length of infant hospital stay minus maternal length of hospital stay. Complications that occurred with each type of delivery were also recorded.

Statistical evaluation of the data was accomplished by the χ^2 test (with Yates correction) and Kruskal-Wallis test in appropriate cases. Differences were considered to be statistically significant at $p < 0.05$.

Results

Comparison of maternal variables among the three groups (Table I) showed no significant difference in maternal age, gestational age, incidence of primiparous women, incidence of postpartum hemorrhage, or incidence of endometritis. There was a significantly shorter maternal postpartum length of hospital stay in those patients who underwent an attempt at breech extraction (2.4 days) than in patients who underwent an attempt at external version (3.7 days) or primary cesarean section (4.4 days) ($p < 0.05$).

Neonatal variables were compared in Table II. There was no difference in birth weights of twin 1 or 2, 1-minute Apgar scores <4, 5-minute Apgar scores <7, incidence of neonatal intensive care unit admissions, respiratory distress syndrome, birth trauma, neonatal deaths, or postpartum infant length of hospital stay after the maternal postpartum length of stay was subtracted from the infant's length of stay. Before the maternal length of stay was considered, there was a significantly longer length of hospital stay for infants delivered by external version (10.1 days) or cesarean section (10.2 days) than in infants delivered by breech extraction (5.0 days). This increase in the length of infant stay in the hospital was a direct result of the increased maternal length of postpartum stay because of the increased incidence of cesarean section in groups A (39.0%) and C (100%) (Table III). The one infant in the primary breech extraction group with a 5-minute Apgar score of 6 had a birth weight of 2160 gm, was not admitted to the neonatal intensive care unit, and went home on postpartum day 3.

Table III shows that patients who underwent a primary attempt at external version had a significantly

TOTAL	41/41 (100%)	55/55 (100%)	—

*Seven successful and nine unsuccessful versions required cesarean section.

higher incidence of cesarean section and were less likely to deliver vaginally as a result of the version attempt than patients who underwent primary breech extraction. In the external version group, the use of epidural anesthesia was not associated with an increase in successful external version (Table IV). Complications during the delivery attempts are listed in Table V. Of the seven successful external versions that required cesarean section, six of the seven operations were performed under emergency circumstances (2 cases for fetal distress, 3 cases of cord prolapse, and 1 compound presentation). The two failed attempts at breech extraction occurred in women who did not receive epidural anesthesia. In both of these cases the uterus contracted, which made breech extraction difficult. One of these patients received halothane anesthesia during the failed attempt at breech extraction. Neither patient received a β-sympathomimetic agent to facilitate uterine relaxation. Neither infant suffered any trauma from the failed attempt at extraction.

Comment

External version of the second nonvertex twin is a relatively new approach to management of the nonvertex twin gestation. Our results do not reflect this as a completely innocuous procedure. Patients in whom an external version was attempted had a vertex vaginal delivery rate of 46% but overall had a cesarean section rate of 39%. Indeed, in 41 attempts at external version, there were 26 successes but only 19 second twins delivered vaginally as a vertex. Because of the higher cesarean section rate, the external version group had a longer postpartum length of stay than patients who underwent primary breech extraction. Although there was no difference in neonatal morbidity or mortality among the three groups, cesarean section was performed for the second twin 39% of the time in patients having an attempt at external version. Approximately one third of these cesarean sections were emergencies for fetal distress, cord prolapse, or compound presentation.

There is a growing body of evidence to suggest that breech vaginal delivery of the second nonvertex twin is a reasonable alternative in infants with birth weights >1500 gm.[5-8] Earlier papers that suggested a worse outcome for the second twin included infants <1500 gm and were reported during a time period when the sec-

Table V. Delivery complications

ond twin was often undiagnosed before delivery.[1, 3, 4] Furthermore, most of these reports were before the use of continuous fetal monitoring and the modern anesthetic techniques of conduction or general anesthesia. In our study, 12 of the 41 infants in the version group and 8 of the 55 breech extraction infants had birth weights <2000 gm. The neonatal and maternal outcomes of these 20 infants were no different from the remainder of the infants in the study.

It should be noted that deliveries at Memorial Medical Center of Long Beach were attended by obstetricians and perinatologists. At Valley Medical Center deliveries were performed by residents, usually without the presence of staff. Thirty-five of the 55 breech extractions and three of the external version patients were from Valley Medical Center. If a bias existed for a worse outcome because of the level of operator experience, it would have been against the breech extraction group because more breech extractions than external versions were performed by residents in training.

The trend toward more successful versions with epidural anesthesia, although not statistically significant, is still striking considering the relatively low numbers (Table IV). Relaxation of the abdominal musculature improves the ability to move the fetal pole and would appear to improve the success rate of external version, even without the use of specific uterine tocolytic therapy. It is possible that such refinements and greater experience may improve the overall success rate with external version of the second twin. However, until better comparative outcome is found and demonstrated, it would be difficult to recommend external version as the preferred method for delivery of the nonvertex second twin. Our data suggest that breech extraction is both a safe and successful primary approach to the delivery of nonvertex second twins weighing more than 1500 gm. Further, these results at least suggest that attempted breech extraction represents a reasonable secondary approach to vaginal delivery of the second nonvertex twin if the external version attempt is unsuccessful.

In conclusion, attempts at external version were associated with a higher failure rate than primary breech extraction. External version was associated with complications that were not seen in either the elective cesarean section or breech extraction groups. There were no differences in terms of neonatal morbidity among the routes of delivery. Primary breech extraction of the second nonvertex twin >1500 gm appears to be a reasonable alternative to either cesarean section or external version.

Magnesium supplementation during pregnancy: A double-blind randomized controlled clinical trial

Baha M. Sibai, MD, Marco A. Villar L., MD, and Eileen Bray, RNC

Memphis, Tennessee

Four hundred young normotensive primigravid women between 13 and 24 weeks' gestation were randomly allocated to one of two study groups. One group received placebo tablets and the other group received 365 mg of elemental magnesium daily (as magnesium aspartate hydrochloride). Three hundred seventy-four patients completed the study, 189 in the placebo group and 185 in the treatment group. There were no significant differences between the two groups regarding serum calcium, uric acid, or electrolyte levels. However, the magnesium-supplemented group had significantly higher magnesium levels at delivery (1.68 ± 0.03 mg/dl vs. 1.56 ± 0.03 mg/dl, $p < 0.01$). There were no significant differences in either systolic or diastolic blood pressures between both groups either at time of enrollment or at subsequent gestational ages later during pregnancy. Analysis of variance for repeated measurements and Fisher's least significant difference testing indicated a significant increase ($p < 0.01$) in blood pressure from the level at the time of enrollment to the level achieved at or beyond 37 weeks' gestation in each group. There were no significant differences between the two groups regarding any of the following parameters: incidences of preeclampsia, fetal growth retardation, preterm labor, birth weight, gestational age at delivery, or number of infants admitted to the special care unit. Magnesium supplementation during pregnancy did not improve pregnancy outcome in our population. (Am J Obstet Gynecol 1989;161:115-9.)

Key words: Oral magnesium aspartate hydrochloride, preeclampsia

The relationship between dietary magnesium deficiency and hypertension has been the subject of several recent experimental and observational studies.[1-5] In addition, in vitro studies on isolated umbilical arteries and veins obtained from term pregnancies showed that the basal tension of these vessels increased when magnesium was withdrawn from the solution and decreased when the magnesium concentration was raised.[6] These experimental findings led Altura et al.[6] to speculate that "progressive hypomagnesemia during pregnancy could produce progressive vasoconstriction resulting in spasm of umbilical and placental arteries and veins, and of other peripheral vessels in the pregnant mother and fetus."

Dietary magnesium deficiency during pregnancy has been implicated in the pathogenesis of preeclampsia, fetal growth retardation, and preterm delivery.[6-9] Data from recent studies reported a decreased incidence of preeclampsia,[6] fetal growth retardation,[7,8] and preterm delivery[8-10] in subjects who received oral magnesium supplementation during pregnancy.

To address these issues, we conducted a double-blind randomized, controlled clinical trial designed to investigate the effects of oral magnesium supplementation during pregnancy on maternal systolic and diastolic blood pressures and the incidence of preeclampsia as primary outcomes. Other outcome variables that were analyzed included changes in serum electrolytes, frequency of preterm delivery, postterm delivery, and fetal growth retardation.

Material and methods

The study population included 400 young (13 to 25 years) normotensive primigravid women who were recruited in our prenatal clinics. All patients were enrolled at 13 to 24 weeks of gestation as determined by obstetric dates and confirmed by ultrasonographic examinations. Patients with associated medical and obstetric complications and those beyond 24 weeks of gestation at the time of the first prenatal visit were excluded from the study. The study was a double-blind randomized, controlled clinical trial that was previously approved by both the Institutional Review Board and the Food and Drug Administration under an investigational new drug number.

After the consent form was signed, patients were allocated randomly to one of two groups, based on a computer-generated list of numbers, using a randomization schedule prepared in advance for the complete population. The same randomization code, standard-

Table I. Clinical characteristics

	Placebo (N = 189)	*Magnesium (N = 185)*
Age (yr)	18.5 ± 0.2	17.8 ± 0.2

At entry	110 ± 0.8	110 ± 0.8
At delivery	125 ± 1.3	126 ± 1.4
Diastolic blood pressure (mm Hg)		
At entry	61 ± 0.7	59 ± 0.8
At delivery	77 ± 1.3	77 ± 1.2
Total weight gain (lbs)	23.8 ± 0.9	25.9 ± 0.9

All values represent mean ± SEM.

ization procedures, and tablets were used in all patients. The code was kept in the outpatient pharmacy department. The women in the magnesium group received six tablets of magnesium-aspartate hydrochloride per day. Each of these tablets contained 60.8 mg of elemental magnesium (a total of 365 mg/day). The placebo group received six matching tablets containing aspartic acid only. The six tablets were divided into three daily doses and were continued until delivery. In addition, all patients received prenatal vitamins containing 200 mg of elemental calcium and 100 mg of elemental magnesium per day.

Total nutrient intake, including detailed description of magnesium intake, was evaluated three times during pregnancy with the 24-hour recall method. At each prenatal visit, patients were questioned regarding tablet intake, compliance, and side effects of medication. Patients were contacted by the research nurse as needed during the study to check compliance and to ensure that they come for their scheduled prenatal visits. On return visits tablet intake and compliance was assessed by a research nurse who performed a tablet count and recorded on the data form the total number of tablets used since the last prenatal visit. Serum magnesium levels at time of delivery also were used to confirm compliance with tablet intake. All patients were followed in our prenatal clinics. Blood pressure and weight were carefully measured at each prenatal visit. Systolic blood pressure was recorded with the appearance of the first Korotkoff sound, and diastolic blood pressure was recorded with the disappearance of the fourth Korotkoff sound. The result of all blood pressure measurements taken between the thirteenth and twenty-fourth weeks of gestation were pooled; the averages were used as baseline values in the adjusted analysis. Laboratory analyses of serum magnesium, calcium, uric acid, and electrolytes were performed at the time of delivery. All clinical decisions regarding management and timing of delivery were made by the attending faculty and house staff.

Analysis of data included comparisons of maternal blood pressures throughout pregnancy and the development of preeclampsia. Preeclampsia was defined as a systolic blood pressure reading of ≥140 mm Hg, diastolic blood pressure of ≥90 mm Hg on two occasions at least 6 hours apart with or without proteinuria, or both. Preeclampsia was classified as mild or severe according to the criteria of the American College of Obstetricians and Gynecologists. All such patients received intravenous magnesium sulfate as prophylaxis against convulsions. Pregnancy outcome included frequency of preterm labor with or without preterm premature rupture of membranes and frequency of postterm pregnancy. Perinatal outcome included gestational age at delivery, birth weight, placental weight, Apgar scores, number of infants admitted to the special care nursery, and the incidence of small-for-gestational-age infants.

Our primary hypothesis was that daily supplementation of 365 mg of elemental magnesium started in the second trimester of pregnancy would reduce the incidence of preeclampsia in a special population with an expected incidence of 20%. A sample size of 400 individuals has a power of 80% to detect a 50% reduction in the incidence of preeclampsia with an $\alpha = 0.05$.

For various reasons (refusal to start tablets, family wishes, to be seen by private physicians or in another clinic) 26 patients never took the medication after enrollment into the study. Eleven were in the placebo group and 15 were in the magnesium group. These subjects were excluded from the study from the onset. All remaining subjects were included in the treatment group to which they were originally randomized, regardless of any follow-up experience.

Statistical analysis used Student's t test, unpaired t test, χ^2, and Fisher's exact test when applicable. For serial blood pressure changes we used analysis of variance for repeated measurements followed by Fisher's least significant difference testing. A p value <0.05 was considered significant.

Results

Twenty-six subjects (11 in the placebo group and 15 in the magnesium group) were excluded for never starting the medication for various reasons. Information was subsequently obtained on 24 of these pregnancies. Two were complicated by preeclampsia and one other pregnancy resulted in fetal demise caused by congenital syphilis. The remainder of the analysis focuses on the 374 patients (189 in the placebo group and 185 in the magnesium group) who started the medication and completed their prenatal care in our clinics.

Table I compares relevant clinical characteristics in the two groups. There were no significant differences between the two groups regarding any of the categories

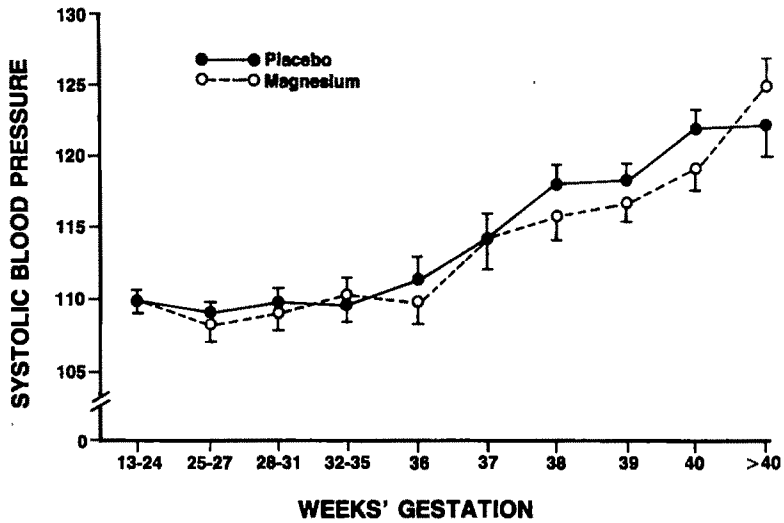

Fig. 1. A comparison of systolic blood pressures between placebo (●——●) and magnesium (o - - - - o). There were no significant differences in systolic blood pressures at any time during pregnancy.

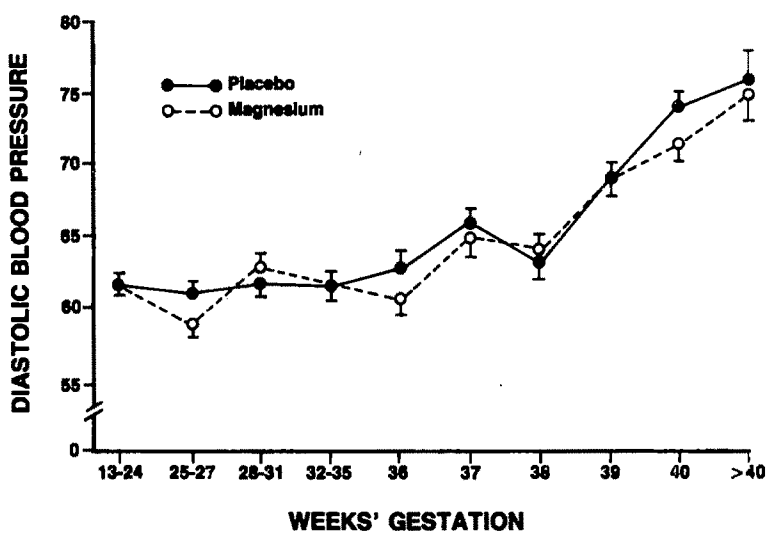

Fig. 2. A comparison of diastolic blood pressures between placebo (●——●) and magnesium (o - - - - o). There were no significant differences in diastolic blood pressures at any time during pregnancy.

studied. In addition there was no difference in racial distribution (90% in the placebo group versus 91% in the magnesium group).

Analysis of the 24-hour recall data revealed no significant difference between the two groups regarding intake of calories, protein, calcium, or magnesium. The mean calcium and magnesium intakes by these patients were 1000 and 260 mg/dl, respectively.

Fourteen subjects in the placebo group and 11 in the magnesium group discontinued intake of tablets before the beginning of the third trimester. The remaining subjects took approximately 90% of the possible number of tablets, which were continued until onset of labor. The major reasons for stopping the medications were gastrointestinal symptoms (nausea, vomiting, diarrhea) and difficulty in swallowing the tablets. The incidence of gastrointestinal symptoms were similar in both groups (7% in the placebo vs. 6% in the magnesium group).

There were no significant differences in either systolic or diastolic blood pressure between the two treatment groups either at time of enrollment or at time of delivery. Figures 1 and 2 describe the mean systolic and diastolic blood pressure values at various gestational

Table II. Laboratory findings at time of delivery

Delivery (gestational age)				
≤36 wk	18	9.5	19	10.2
≥42 wk	6	3.2	6	3.8

*No significant difference for any of the categories studied.

ages in both groups. There were no significant differences between the two groups regarding blood pressure changes throughout gestation (by analysis of variance for repeated measurements). However, within each group analysis of data with analysis of variance for repeated measurements followed by Fisher's least significant difference testing revealed a significant increase ($p < 0.01$) of both systolic and diastolic blood pressure values recorded at the time of enrollment compared to those recorded at or beyond 37 weeks of gestation.

Calculations were repeated after excluding patients who did not take medications during the third trimester from the analysis. These exclusions did not affect the above changes in blood pressure. Similar calculations were repeated after patients in both groups who developed preeclampsia were excluded. There were no differences in either systolic or diastolic blood pressures in subjects who remained normotensive in the two treatment groups.

Serum levels of magnesium, calcium, sodium, potassium, and uric acid were obtained in the majority of patients who continued medication throughout pregnancy. Table II compares the respective serum levels of these measurements in the two groups. The magnesium-supplemented group had statistically significantly higher serum magnesium levels than the placebo group. However, the serum magnesium levels achieved in the magnesium group were in the ranges that have no clinical significance.

Table III summarizes the pregnancy outcome in the two groups. The incidence of preeclampsia was 18.5% in the placebo group and 17.3% in the magnesium group. Calculations were repeated after excluding three patients from the placebo group and two from the magnesium group who developed preeclampsia, and patients who stopped medications before the third trimester. The incidence of preeclampsia remained similar in both groups. We observed no statistically significant differences between treatment groups with respect to preterm labor, delivery at or before 36 weeks' gestation, and postterm pregnancy.

Table IV compares the perinatal outcome of the two treatment groups. There were no statistically significant differences between the treatment groups with respect to birth weight, incidence of fetal growth retardation, Apgar score, or number of infants admitted to the special care nursery. There was one miscarriage at 17 weeks' gestation and one neonatal death at 26 weeks' gestation in the placebo group. In the magnesium group, there was one miscarriage at 20 weeks' gestation and a neonatal death from multiple congenital anomalies at 35 weeks' gestation.

Comment

Serum magnesium levels are usually lower during pregnancy compared with the nonpregnant state, and are further reduced in the presence of preterm labor.[10] In patients with preeclampsia magnesium levels were reported to be lower[11] or similar to[12] values observed in normotensive pregnancies. Because parenteral magnesium sulfate is the drug of choice in the treatment of preeclampsia, some authors suggested an etiologic relationship between magnesium deficiency and preeclampsia.[6, 7]

In a retrospective study, Conradt et al.[7] compared the pregnancy outcome in 4023 low-risk pregnancies to that in 882 pregnancies considered to be at risk for preterm delivery and fetal growth retardation. The high-risk group was treated with β-sympathomimetic agents in combination with magnesium aspartate hydrochloride. The incidence of preeclampsia was 2% in the no-treatment group and 0% in the treated group. The incidence of fetal growth retardation in the treated group was similar to that in the low-risk group. The authors concluded that magnesium supplementation prevents preeclampsia and fetal growth retardation.

In their double-blind study of magnesium supplementation in pregnancy, Spätling and Spätling[9] found that magnesium supplementation was associated with significantly fewer maternal hospitalizations and with a reduction in both preterm labor and number of newborns admitted to the intensive care unit. The differences in outcome between the magnesium and placebo groups were primarily related to the significantly higher number of patients in the placebo group with a diagnosis of antepartum hemorrhage (17 vs 4) and incompetent cervix (17 vs 8). It is very unlikely that magnesium supplementation will prevent such complications. Hence, differences in outcome were related to the fact that the two groups were not comparable.

The recommended daily allowance for dietary magnesium during pregnancy is 450 mg/day.[5] Ashe et al.[13] observed that in middle-class pregnant women (students and personnel at the University of Tennessee, Knoxville) the magnesium intake was only 60% of the recommended allowance of pregnant women. It is conceivable that in indigent pregnant women, nutritional magnesium deficiency is much worse. In a preliminary study of 500 patients at our prenatal clinics, approximately 75% of the patients took less than two thirds of the recommended dietary allowances of magnesium.

Our study was designed to evaluate the effects of oral magnesium supplementation during pregnancy on the incidence of preeclampsia in a group of patients judged to be at a very high risk for the development of the disease (expected incidence of 20%). The population included a homogeneous group of young primigravid women who were indigent and mostly black (90%).

Our findings support no evidence of any benefit of magnesium supplementation on the frequency of either preeclampsia or fetal growth retardation. In addition, magnesium supplementation did not influence either the systolic or diastolic blood pressure in these patients. These findings are similar to those reported recently by Spätling and Spätling.[9] In contrast, we did not find any differences in frequency of preterm delivery and number of admissions to a special care nursery between the placebo and the magnesium supplemented group. Our study did not have adequate size to detect small differences in the incidence of preterm labor. However, when the incidence of preterm labor in both groups is considered, a sample size 10 times larger than the number studied here would not have shown any difference.

The results of the present investigation do not support the conclusion of the investigation by Conradt et al.[7] Perhaps the differences between both studies may be related to study design (retrospective in nature), the population studied (heterogeneous group of patients with various diagnoses) and the use of β-sympathomimetic agents in the study by Conradt et al.

In summary, magnesium supplementation during pregnancy did not reduce the incidence of either preeclampsia or fetal growth retardation in our population.

We thank Dr. Frank Douglas and Ms. Rita Geiser, Ciba-Geigy Corporation, for their contribution to this investigation.

Methicillin-resistant staphylococcal mastitis

Charles Kalstone, MD
Miami, Florida

A postpartum patient had a unilateral breast infection that responded to cephalosporin treatment. During therapy, the contralateral breast developed a methicillin-resistant *Staphylococcus aureus* infection. The patient was hospitalized and treated successfully with intravenous vancomycin. Obstetricians should be alert to this possibility when treating patients with postpartum mastitis. (AM J OBSTET GYNECOL 1989;161:120.)

Key words: Postpartum mastitis, *Staphylococcus aureus*, methicillin-resistant organism

We report a case of postpartum mastitis caused by a methicillin-resistant *Staphylococcus aureus* infection. When such infection occurs, the usual antimicrobial therapy for mastitis may not be effective.

Case report

A 24-year-old primiparous woman who had a normal vaginal delivery 1 month previously was breast-feeding and developed mastitis in the left breast as evidenced by unilateral pain, tenderness, redness, and a fever of 102° F. Cephalexin, 500 mg every 6 hours, was prescribed and within 24 hours the patient was afebrile, felt well, and the breast tenderness was resolving. She continued to nurse. Two days later, while she was still taking cephalexin, she developed a fever of 103° F, pain, tenderness, and redness in the opposite breast. The initial (left) breast infection had completely resolved.

The development of mastitis in the contralateral breast while the patient was taking cephalosporin was thought to be caused by a methicillin-resistant *Staphylococcus aureus* infection. The patient was admitted to the hospital and treated with intravenous vancomycin, 500 mg every 6 hours. Cephalexin was discontinued. Two blood cultures were obtained and these subsequently revealed no growth. A Gram stain of the milk expressed from the inflamed right breast did not show any organisms, but the culture later grew a methicillin-resistant *Staphylococcus aureus*, sensitive to vancomycin and Bactrim. The patient was advised to discontinue nursing and was given bromocriptine mesylate and was treated with intravenous vancomycin for 5 days. Within 24 hours she was afebrile and remained so; the breast inflammation resolved and she was discharged with Bactrim for 5 additional days. She had no further problems. Her infant had no signs of staphylococcal infection. An epidemiologic search did not reveal the source of the maternal infection.

Comment

Since the incidence of methicillin-resistant staphylococcal infections is increasing, it seems logical that they will be encountered in postpartum mastitis. It had been standard practice to prescribe ampicillin in such cases. Even though the organism is usually a penicillinase-producing *Staphylococcus aureus*, the mastitis usually responds.[1, 2] Because of concerns about penicillin-resistant *Staphylococcus aureus* strains, standard treatment changed to a cephalosporin or cloxacillin.[3] This case demonstrates that postpartum mastitis may not respond to these drugs or that it may develop in the opposite breast despite them. These patients should have cultures and be treated for a methicillin-resistant *Staphylococcus aureus* infection, either with intravenous vancomycin or oral Bactrim, if the organisms are sensitive.

Gestational trophoblastic disease: A case-control study from the People's Republic of China

Louise A. Brinton, PhD,[a] Bao-Zhen Wu, MD,[b] Wen Wang, MD,[c] Abby G. Ershow, ScD,[d] Hong-Zhao Song, MD,[b] Jun-Yao Li, MD,[c] Michael B. Bracken, PhD,[e] and William J. Blot, PhD[d]

Bethesda, Maryland, Beijing, People's Republic of China, and New Haven, Connecticut

A case-control study involving 331 patients with complete hydatidiform mole and 662 community controls matched to the cases on age and timing of pregnancy was conducted in Beijing, China. A history of a term birth was associated with reduced risk (odds ratio = 0.6, 95% confidence interval 0.4 to 0.9), with some evidence of further decrease with multiple births. Previous spontaneous abortions were not related to risk, although those with a prior induced abortion were at elevated risk, particularly if two or more abortions were involved (odds ratio = 2.8, 95% confidence interval 1.4 to 5.7). A history of having sought medical advice for infertility was associated with reduced risk (odds ratio = 0.5, 95% confidence interval 0.2 to 0.8), but those who reported use of herbal medicines during a first trimester of a previous pregnancy were at excess risk (odds ratio = 2.2, 95% confidence interval 1.3 to 3.6). In addition, a statistically significant trend in risk was observed with years of oral contraceptive use (odds ratio = 2.6, 95% confidence interval 0.9 to 6.9 for ≥4 years of use). Dietary habits and family histories of cancer or trophoblastic disease were not related to risk in this study. (Am J Obstet Gynecol 1989;161:121-7.)

Key words: Hydatidiform mole, reproduction, infertility, contraception, epidemiology

Hydatidiform mole, an abnormal proliferation of the trophoblast, has long been of interest to clinicians as a complication of pregnancy that frequently progresses to invasive disease or choriocarcinoma. Hydatidiform mole can be classified into two distinct entities on the basis of pathologic and cytogenetic criteria.[1] The most clinically important entity, complete mole, usually has a 46,XX chromosomal constitution. This is a consequence of an anucleate egg being fertilized by a haploid sperm; subsequently cell division restores the normal chromosome number. In contrast, partial moles contain maternal chromosomes in the karyotype and have a triploid genotype.

Although the natural history of hydatidiform mole is relatively well understood, etiologic factors have received much less attention. It is recognized that risk increases significantly with late maternal age and to a lesser extent with pregnancies at very young ages.[2, 3] The influence of other reproductive factors, however, remains to be established. Other possible risk factors include Oriental race, low socioeconomic status, viral or parasitic infections, oral contraceptive use, consanguinity, and immunogenetic factors, although most of these variables have been suggested on the basis of case series rather than analytic studies.

An incidence survey of hydatidiform mole in more than three million women in the People's Republic of China[4] stimulated interest in further defining etiologic factors. Thus in 1982 a large case-control study was initiated in Beijing to evaluate the influence of a variety of environmental and genetic factors on risk of gestational trophoblastic disease.

Material and methods

This case-control study, which was begun in April 1984 after a 1-year pilot study, included 5 years of retrospectively ascertained and 2 years of prospectively ascertained cases from eight Beijing hospitals. Although the study identified all Beijing residents diagnosed with gestational trophoblastic disease during the study period, patients diagnosed with partial hydatidiform mole (i.e., those with embryonal tissue in the evacuated conceptus) were not enrolled because of small numbers ($n = 7$) and presumed differences in etiology and pathogenesis. Case definitions of study subjects were based on criteria established by the World Health Organization,[5] as reported in another investigation of Chinese women.[5] All cases of complete hydatidiform mole without invasive complications were pathologically confirmed. A lower proportion of malignant consequences were pathologically confirmed (36% of retrospective and 81% of prospective cases), primarily because of the nonsurgical treatment used to

preserve reproductive function. In the absence of pathologic confirmation, a diagnosis of invasive mole was assigned on the basis of human chorionic gonadotropin determinations, x-ray examinations, and the disease being preceded by a molar pregnancy within the previous year. A total of 260 patients with noninvasive complete hydatidiform mole, 157 with invasive mole, and 34 with choriocarcinoma were ascertained during the study period.

Each case was personally interviewed by trained interviewers. Interviews with prospectively ascertained cases were conducted in hospitals, while retrospectively ascertained patients were interviewed in their homes. Interviews took approximately 1 hour to complete and obtained detailed information on demographics, occupation, pregnancy history, infertility, menstrual history, contraceptive use, medical history, marriages, family history of hydatidiform mole and choriocarcinoma, and cancer, smoking, and dietary practices. Interviews were obtained from 358 of the 451 eligible cases (79.4%). Reasons for nonresponse related primarily to difficulties in locating subjects (15.5%), with few subjects being excluded because of death (1.8%) or refusal to participate (3.3%).

For each interviewed case in the study, two population controls were selected. Depending on whether the case resided in an urban or a rural area, the first unit of selection was the same street office or commune as that of the case. Within these areas, a random selection was made of one neighborhood committee or production brigade (residential units of approximately 900 families); these were visited to abstract information from census lists on all women who were within 2 years of age of the identified case. These potential controls were located and information on the timing of all of their pregnancies was obtained. Control subjects were then selected so that they had had a pregnancy within 1 year of the date of termination of the molar pregnancy of the matched case. Control subjects were interviewed in their homes by the same questionnaire approach as that used with retrospective cases.

Because the number of women with choriocarcinoma was small (n = 27), these subjects were not included in this analysis. Included for analysis were 331 patients with complete hydatidiform mole (189 with noninvasive mole and 142 with invasive mole) and 662 matched controls.

Since study subjects were interviewed at variable times after diagnosis, it was necessary to truncate exposure information in the analysis. Reproductive information considered only pregnancies occurring before the diagnostic molar pregnancy (and a comparable period for matched controls). Contraceptive information was truncated at a common date 6 months before the earliest termination date of the last non-molar pregnancy of the case or her matched controls.

The dietary history inquired about use of cooking oils and usual frequency of consumption of 32 food and beverage items 5 years before interview. The history focused on alcoholic beverages and foods high in vitamin A (retinol and carotene sources) and folic acid. The yearly frequencies of intake of various food items

were adjusted for length of season and summed to form food groups such as staple foods, animal foods, high vitamin A foods, and fruits. The control distributions of the two case series were each divided into quartiles for use as exposure levels in risk estimates.

For evaluating effects of exposure factors related to complete hydatidiform mole, the measure of association used was the odds ratio, an estimate of the relative risk. Unmatched logistic regression analyses were performed to obtain maximum likelihood estimates of the odds ratios and 95% confidence intervals, adjusted for confounding variables. Two-tailed tests for trend in the logistic analyses were obtained by categorizing the exposure variable, assigning the score j to the *jth* exposure level of the categoric variable, and treating the scored variable as a continuous variable. Because matching was done in the study design, matched logistic regression analyses were also done. Since these analyses produced results nearly identical to those derived from the unmatched analyses, the latter were chosen for presentation.

Results

Table I shows selected sociodemographic variables for the patients with complete hydatidiform mole and their respective controls. The mean age of both the patients and the controls was 29.2 years.

Cases and controls were compared on a number of sociodemographic variables, including education, family size, total family income in 1978 (before diagnosis of disease in any study subjects), and income per person supported. No appreciable differences were seen between cases and controls for these variables.

Analyses of reproductive factors showed a protective effect associated with ever having had a term live birth or stillbirth (odds ratio = 0.6, 95% confidence interval 0.4 to 0.9). There was some indication of decreasing risk with increasing numbers of term births (Table II), although further decreases in risk were not observed for more than two births. After controlling for number of term births, there was no effect on risk of a history of prior spontaneous abortion. However, an elevated risk was associated with a history of induced abortion, particularly if two or more abortions were reported (odds ratio = 2.8, 95% confidence interval 1.4 to 5.7).

Although subjects were matched on age of index pregnancy, preventing assessment of this as a risk factor, it was of interest to examine among previously pregnant women whether risk was influenced by age at first pregnancy. There was an increase in risk associated with a first pregnancy before age 22, but there were no clear trends in risk beyond this age. No striking associations were found for factors related to reproduction, including ever having had a low-birth-weight baby (<2.3 kg) or a baby with a birth defect, delivery by cesarean section, or history of breast-feeding.

A history of having sought medical advice for infertility, although reported by a limited number of study

subjects, was associated with a significant reduction in risk (odds ratio = 0.5, 95% confidence interval 0.2 to 0.8) (Table III). Use of herbal medicines during the first trimester of prior pregnancies, however, was associated with an elevated risk (odds ratio = 2.2, 95% confidence interval 1.3 to 3.6). During prior pregnancies, comparable histories of exposure to vitamins, progestogens, and estrogens (the latter not shown because of limited numbers) revealed no significant differences between cases and controls.

Table IV presents results according to years of use of oral contraceptives and intrauterine contraceptive devices (IUDs). Risk increased significantly with duration of pill use, with the odds ratio being 2.6 (95% confidence interval 0.9 to 6.9) for users of 4 or more years. This association persisted after control for a variety of other factors, including infertility, which other studies have linked to oral contraceptive use. Similarly, the infertility relationships were unaltered when examined only among non–oral contraceptive users. Years of use of IUDs did not significantly relate to risk.

The occurrence of complete hydatidiform mole was evaluated further according to several menstrual and anthropometric factors (Table V). Age at menarche was not associated with risk, despite a fair amount of range in ages at onset. Menstrual irregularity, reported by only a small proportion of the study subjects, was also not associated with risk (odds ratio = 1.1). Other factors examined included whether sexual intercourse was avoided during menses and how often the perineum was washed, but neither of these behaviors was predictive of risk.

Adult height and weight before a first pregnancy did not appear to relate to risk of complete mole, nor did more refined measures of body mass, including Quetelet's index (weight/height^2).

Risk was evaluated in relation to a number of previous diseases, including several experienced during the first trimester of previous pregnancies (Table VI). Although no significant associations were observed with a variety of conditions or diseases during pregnancy, including toxemia, influenza, and other conditions, subjects reporting toxemia were at a nonsignificantly elevated risk (odds ratio = 1.7, 95% confidence interval

0.9 to 2.8). Diseases experienced at other times, including cervicitis, abnormal genital bleeding, and anemia, were not predictive of risk.

There was no apparent relationship between risk and yearly intake of staple foods, animal source foods, vegetables, legumes, or fruits. There also was no consistent dose-response relationship of risk with foods rich in retinol, carotene, ascorbic acid, folic acid, or riboflavin. Intake of crude cottonseed oil, a source of the reproductive toxin gossypol, was also generally not related to complete hydatidiform mole.

No clear trends of disease were observed with either

Table VII. Odds ratios of complete hydatidiform mole by age difference between subject and husband, family history of cancer, smoking, and alcohol consumption

	Cases	*Controls*	*Odds ratio**	*95% Confidence interval*

†Limited to subjects married only once. Unknowns eliminated from analysis.

age of the father at conception of the molar pregnancy (not shown) or with the age difference between the study subject and her husband (Table VII). Family histories of cancer in first-degree relatives or husbands were also not predictive of risk, nor were family histories of gestational trophoblastic diseases, which were not reported for any of the mothers or sisters of the study subjects.

Ever having smoked cigarettes was also not associated with disease risk, although few subjects reported such a history. There was some evidence that the subjects with the highest intake of alcohol (more than 52 drinks per year) were at an elevated risk (odds ratio = 2.1, 95% confidence interval 1.2 to 3.9), although alcohol consumption at lower levels was not related to risk.

Finally, relationships were examined according to whether the case was retrospectively or prospectively ascertained, as well as by the occurrence of invasive complications. No major differences in results were observed between the retrospective and prospective series. Number of prior abortions was a stronger risk factor for invasive mole, whereas oral contraceptive usage more adversely affected noninvasive mole. Other risk factors operated similarly between the two case series.

Comment

Similar to other studies,[6,7] we found that a history of a prior term birth was associated with reduced risk for complete hydatidiform mole (odds ratio = 0.6) and that there was some evidence of a decreasing trend in risk with number of births. Similar to one other study[6] but in contrast with others,[7,8] we found no relationship of risk with the occurrence of prior spontaneous abortions. It is of note that we observed a significant relationship of risk to prior induced abortions, particularly if two or more abortions were involved. Other studies have been unable to assess this association in detail because of limited reporting of the procedure. However, our finding was difficult to interpret because of the possibility of recall bias and the absence of reasons for the terminations. Further investigation appears warranted.

A history of infertility in this study was not associated with increased risk, as reported by La Vecchia et al.[8] but not by Messerli et al.[6] In fact, there was some evidence of a protective effect, although the nature of the infertility was somewhat unusual since all subjects were required to have been pregnant at least once. In addition, histories were limited to women who had sought medical advice for their problems, and numbers of such women were small. Of particular interest was an elevated risk associated with use of herbal medicines during the first trimester of previous pregnancies. Although recall bias or uncontrolled confounding cannot be ruled out, it is of interest that we did not find a similar association with other preparations used during pregnancy, including progestogens, estrogens, or vitamins. The absence of information on reasons for use of herbal medicines prevents an assessment of whether

the increased risk is associated with the indication for use or the actual preparation. A history of abnormal bleeding did not appear to explain the relationship with herbal medicines, but other underlying disorders such as nausea, vomiting, or threatened miscarriage cannot be dismissed. It is possible that the herbal medicines, which are composed of a complex of natural and synthetic constituents, may have mutagenic or carcinogenic properties. Although our findings are of interest given laboratory findings that choriocarcinoma can be induced in patas monkeys by exposure to ethylnitrosourea during pregnancy,[9] further analytic studies in humans are needed.

Of further interest is the significant relationship that we observed between years of oral contraceptive use and risk of complete mole, where users of ≥4 years were at a nonsignificant 2.6-fold risk. Although the finding was based on small numbers and a biologic mechanism is unclear, the association is consistent with an effect observed by Berkowitz et al.,[10] although in that study the relationship appeared to be significantly confounded by IUD use. Studies by Messerli et al.[6] and La Vecchia et al.,[8] however, failed to find an effect of oral contraceptives on the occurrence of hydatidiform mole. Other studies have suggested that oral contraceptives may increase the risk of malignant sequelae after molar evacuation by providing a tumor-stimulating effect.[11] In one study[12] this effect was restricted to users of high-dose estrogens, although in other studies[10,13] there was no effect of the pill on postmolar complications, regardless of the preparations used. However, in our study, pill associations were stronger for noninvasive mole than for invasive mole.

Our study also provided the opportunity to evaluate a number of risk factors suggested by other investigators. Although late paternal age has been suggested in one study to increase the risk of trophoblastic diseases,[14] other investigations,[6,15] as well as our own, failed to confirm this. Cigarette smoking has also been linked with the occurrence of trophoblastic diseases,[8] but this could not be fully examined in our study as so few Beijing women smoked cigarettes. Furthermore, our results failed to indicate a relationship of risk to any dietary variables, including carotene, which has been suggested as a protective factor for complete hydatidiform mole.[10] However, this may be due in part to the difficulty of studying dietary exposures in China, where the food supply comprises relatively few items in any one locale and there is little heterogeneity in intake among subjects. Finally, other studies have hinted that a family history of trophoblastic diseases[16] might be important etiologic factors, but our study was unable to detect such an effect.

Although genetic investigators indicate that complete hydatidiform mole originates at fertilization, our results suggest that influences operating earlier, possibly on the susceptibility of the genetic material in the ovum, may also be involved. It is well established that a major predictor of risk is maternal age, but our results indicate that even after controlling for this factor, other reproductive factors seem to be etiologically important. In particular, the protective effect of a term pregnancy on risk of a subsequent molar pregnancy was apparent, whereas unnaturally terminated pregnancies increased risk. Furthermore, this study raises new questions regarding chemical and hormonal influences, particularly oral contraceptives, supporting the need for further detailed investigations.

Randomized treatment of mucopurulent cervicitis with doxycycline or amoxicillin

Jorma Paavonen, MD, Pacita L. Roberts, MS, Claire E. Stevens, MA, PA, Pål Wølner-Hanssen, MD, Robert C. Brunham, MD, Sharon Hillier, PhD, Walter E. Stamm, MD, Cho-Chou Kuo, MD, Timothy DeRouen, PhD, King K. Holmes, MD, PhD, and David A. Eschenbach, MD

Seattle, Washington

A randomized trial of doxycycline versus amoxicillin was performed to treat mucopurulent cervicitis. *Chlamydia trachomatis*, the most common single agent associated with mucopurulent cervicitis, was isolated from 30 (47%) and *Neisseria gonorrhoeae* from five (8%) of 64 patients. Patients were followed up for 3 months, and the effect of treatment was assessed by clinical (presence of endocervical mucopus, cervicitis severity score, and number of polymorphonuclear leukocytes on Gram-stained smears of endocervical secretions) and microbiologic criteria. Doxycycline and amoxicillin were equally effective for treating chlamydial and nonchlamydial cervicitis. However, endocervical mucopus was still present in 18% of the patients in both treatment groups after 2 months and in 23% of the doxycycline group and 33% of the amoxicillin group after 3 months of therapy. The cause of persistent/recurrent mucopus after antimicrobial treatment was not explained by relapse or reinfection with *Chlamydia trachomatis, Neisseria gonorrhoeae*, genital mycoplasmas, or *Gardnerella vaginalis*, but persistence was associated with the degree of cervical ectopy. (AM J OBSTET GYNECOL 1989;161:128-35.)

Key words: *Chlamydia trachomatis, Neisseria gonorrhoeae,* mucopurulent cervicitis, treatment of mucopurulent cervicitis

Chlamydia trachomatis and *Neisseria gonorrhoeae* cause mucupurulent cervicitis.[103] Mucopurulent cervicitis represents an important reservoir for upper genital tract infection in women. Acute pelvic inflammatory disease develops in 10% to 20% of women with *C. trachomatis* or *N. gonorrhoeae* cervicitis.[4] However, only about half of women with mucopurulent cervicitis have chlamydial or gonococcal cervical infection,[2] and the cause of the cervicitis and the risk of pelvic inflammatory disease among women with nonchlamydial/nongonococcal cervicitis is unknown.

Women with mucopurulent cervicitis have cytologic,[5] colposcopic,[6] and histologic[7] abnormalities regardless of whether *C. trachomatis* or *N. gonorrhoeae* is present. Observation of the clinical characteristics of cervicitis provides the only practical manner to monitor the effects of antimicrobial therapy among patients not infected with these two organisms. The eradication of *C. trachomatis* and *N. gonorrhoeae* from the cervix by penicillin-tetracycline regimens has been well documented.[8] However, the effect of antimicrobial therapy on clinical features of cervicitis and the treatment of nonchlamydial, nongonococcal cervicitis has not been reported, and more information is required of the treatment of all varieties of cervicitis. In this study we compared the effects of two antimicrobials on the results of cervical cultures, the clinical features of cervicitis, and polymorphonuclear leukocytes observed on Gram-stained smears of cervical secretions.

Material and methods

Study population. Nonpregnant women with gross endocervical mucopus who attended the Seattle–King County Sexually Transmitted Diseases Clinic at Harborview Medical Center in Seattle were eligible for study. Consecutive women who agreed to the randomized treatment section of the study were selected from a larger group of women with cervicitis previously described.[2] Patients were included if they had a yellow mucopurulent endocervical discharge as observed on a white cotton swab as previously described.[1,2] Exclusion criteria were under 16 years old, allergy to either study drug, ingestion of antimicrobial drugs within the prior month, use of intrauterine contraceptive device, or history of pelvic inflammatory disease. Five additional women with menses were excluded because they could not be evaluated for the presence of endocervical mu-

No. with bacterial vaginosis (%)	8/23 (35)	7/16 (44)

STD, Sexually transmitted disease.

copus. Seventy-two women were initially enrolled into the study, and the 64 women who returned for one or more follow-up visits are included in these analyses.

Patient evaluation. A standardized interview was obtained concerning menstrual, contraceptive, sexual, and a prior sexually transmitted disease history. During the speculum examination, the appearance of the cervix was observed both before and after vaginal material was removed from the portio with a large swab. The color of cervical secretions viewed on a white cotton swab was classified as clear, white, cloudy, or yellow. The severity of inflammation of the cervical epithelium was assessed by scoring the degree of (1) mucosal bleeding induced by swabbing the cervix, (2) presence of erythema, and (3) presence of edema in the zone of ectopy and the transformation zone as observed with the unaided eye. Each finding was scored as 0 (none or normal, 1+ (mild), 2+ (moderate), or 3+ (severe), and the sum of these scores represented the cervicitis severity score.[1, 9] Mild bleeding was defined as a few two drops of blood after repetitive swab sampling of the cervix. Bleeding that soaked a Q-tip swab with the first or second swab sampling was defined as moderate bleeding, and bleeding down the face of the cervix with the first swab or vaginal pooling of blood was defined as severe bleeding. Erythema was defined as an abnormal red color in the area of ectopy (transformation zone) subjectively graded as mild, moderate, or severe redness. Edema was defined as an elevation of the area of ectopy above the level of surrounding ectocervical squamous epithelium and was subjectively graded as mild, moderate, or severe elevation.

Collection of specimens. Urethral and endocervical specimens were obtained for isolation of *C. trachomatis* as previously described.[2] Endocervical specimens were obtained for *C. trachomatis* with sterile Dacron swabs and for other organisms with sterile cotton swabs. The swabs for *C. trachomatis* and herpes simplex virus cultures were placed in transport media as described elsewhere.[2] The remaining swabs were directly placed on the following media: Thayer-Martin medium for *Neisseria gonorrhoeae,* human blood Tween (HBT) medium for *Gardnerella vaginalis,* Diamond's medium for *Trichomonas vaginalis,* and agar and broth media for *Ureaplasma urealyticum* and *Mycoplasma hominis,* as previously described.[2] Aliquots of vaginal fluid were mixed with saline solution and microscopically examined for the presence of clue cells and motile trichomonads. A diagnosis of bacterial vaginosis was made by previously described Gram stain characteristics[10] when the number of small gram-negative bacilli and gram-positive cocci was greater than the number of *Lactobacillus* morphotypes.

Definition of mucopurulent cervicitis. After the ectocervix was wiped clean with a large cotton swab, endocervical mucus was collected on a white-tipped swab, with care taken to avoid contamination by vaginal secretions. The presence of a yellow mucopurulent endocervical discharge (mucopus) as observed on the white cotton swab was used to diagnose mucopurulent cervicitis.[1] The swab was rolled onto a 2 cm^2 area of a glass microscope slide. The smear was air dried and Gram stained by the rapid method. Slides were scanned at a magnification of 100 to evaluate the presence and amount of cervical mucus, to look for squamous cells, and to identify areas of mucus that appeared to contain inflammatory cells. Most often polymorphonuclear leu-

*Follow-up visits after initiation of treatment.

kocytes were distributed uniformly in cervical mucus, but in cases in which they were distributed in a patchy fashion, representative areas containing the densest concentration of such leukocytes were selected. The number of polymorphonuclear leukocytes per microscopic field at a magnification of 1000 in five nonadjacent fields was then established with use of an oil lens (polymorphonuclear leukocyte count). Details of the examination have been published.[1]

Microbiologic studies. *C. trachomatis* was isolated on idoxuridine treated McCoy cells, and *N. gonorrhoeae* was identified by sugar fermentation as described.[1] Specimens from inoculated Diamond's medium[11] were microscopically examined every other day for 1 week to identify *T. vaginalis*. The methods used to identify herpes simplex virus, *U. urealyticum*, *M. hominis*, and *G. vaginalis* have been described.[2]

Treatment and follow-up. Patients were randomly assigned by a consecutive closed envelope draw to receive 100 mg of oral doxycycline twice daily for 14 days or oral amoxicillin, 3 gm, with 1 gm probenecid as an initial dose, followed by 500 mg three times daily for 14 days. Patients were asked to avoid sexual activity during the treatment, encourage their sexual partners of the past month to come for evaluation and treatment to the same clinic, use condoms until after the final follow-up visit, and return for follow-up visits at 4, 8, and 12 weeks after treatment was initiated. At follow-up visits, the presence or absence of mucopurulent cervicitis and other genital infections was reassessed, and all microscopic and microbiologic studies performed at the first visit were repeated.

Statistical analyses. Statistical comparisons between treatment groups for demographic, behavioral, clinical, and microbiologic variables used Fisher's exact test for categoric variables with dichotomous outcomes, and the Student *t* test for continuous variables. Comparisons between treatment groups for polymorphonuclear leukocyte counts and cervicitis scores were made at 4-, 8-, and 12-week visits with the use of the Mann-Whitney rank-sum test. Within treatment groups, statistical significance of changes between visits was determined with Wilcoxon's signed rank test for paired data. Logistic regression analysis was used to test effects while adjusting for potentially confounding variables.[12]

Results

Microbiologic results of therapy. Sixty-four patients with mucopurulent cervicitis were enrolled and returned for one or more follow-up visits; 37 received doxycycline and 27 received amoxicillin. Of these patients, 57 were examined at 1 month, 51 at 2 months, and 44 at 3 months. The treatment groups were comparable with respect to age, race, marital status, education, gravidity, parity, contraceptive use, age at first intercourse, number of lifetime sexual partners, and past history of sexually transmitted diseases (Table I). *C. trachomatis* alone was isolated from the cervix from 25 (39%) of the 64 patients, and both *C. trachomatis* and *N. gonorrhoeae* were isolated from five (8%) of the

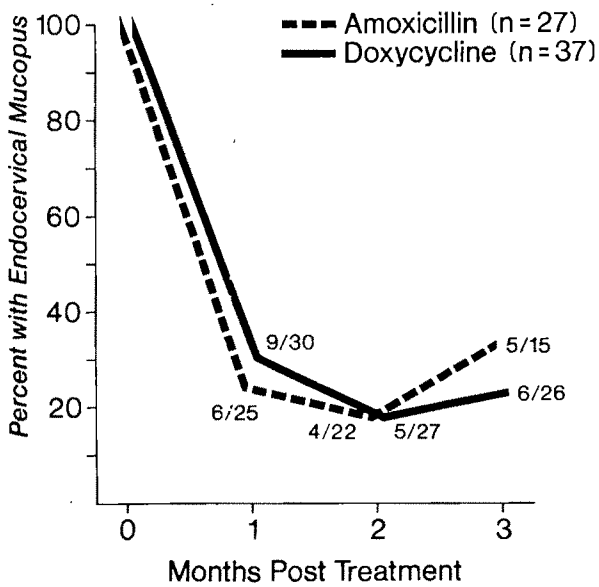

Fig. 1. Number of patients with endocervical mucopus over number of patients examined (%) before treatment and at 1, 2, and 3 month visits after starting treatment with doxycycline or amoxicillin.

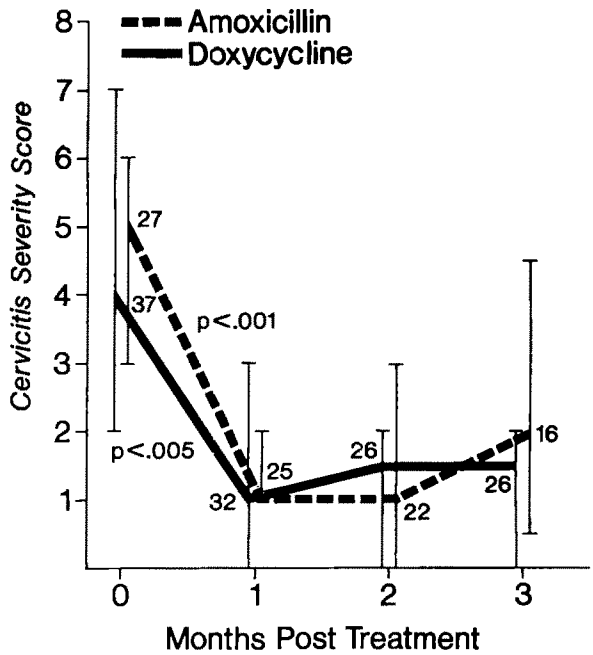

Fig. 2. Median cervicitis severity score with twenty-fifth and seventy-fifth percentiles before treatment and at 1, 2, and 3 months after starting treatment with doxycycline or amoxicillin (number indicates number of observations).

women. *N. gonorrhoeae* was not isolated without *C. trachomatis*. Neither organism was found in 34 (53%) of the women. At enrollment, the prevalence of *C. trachomatis, N. gonorrhoeae,* herpes simplex virus, *U. urealyticum, M. hominis,* and *G. vaginalis* was similar in the two treatment groups.

The presence of selected organisms at each of the follow-up visits stratified for the presence or absence of the organism at enrollment is tabulated in Table II for the doxycycline- and amoxicillin-treated groups. Both antibiotic regimens appeared effective in eradicating *C. trachomatis* and *N. gonorrhoeae* as determined at the 3-month follow-up visit. Among women positive for *C. trachomatis* at the initial visit, *C. trachomatis* was reisolated at any follow-up visit in one (6%) of 17 following doxycycline treatment and in two (18%) of 11 following amoxicillin treatment (NS). Among women negative for *C. trachomatis* at the enrollment visit, *C. trachomatis* was isolated at any follow-up visit from one (5%) of 19 patients given doxycycline and two (13%) of 15 given amoxicillin (NS). Thus *C. trachomatis* was isolated from two (6%) of 36 patients after doxycycline treatment and from four (15%) of 26 patients after amoxicillin treatment (NS). *N. gonorrhoeae* was not reisolated after therapy.

Neither regimen effectively eradicated *U. urealyticum, M. hominis,* or *G. vaginalis* (Table II). Among patients who were initially *U. urealyticum* positive, *U. urealyticum* was reisolated after therapy from 16 (57%) of 28 patients treated with doxycycline and from 18 (95%) of 19 patients treated with amoxicillin ($p = 0.005$). Although doxycycline was significantly more effective than amoxicillin in the eradication of *U. urealyticum,* the persistence of mucopurulent cervicitis was not significantly related to subsequent *U. urealyticum* isolation. Also, no association was found between mucopurulent cervicitis after therapy and the reisolation of *M. hominis* or *G. vaginalis.*

Effects of therapy on mucopus and cervical appearance. Fig. 1 shows the proportion of patients with endocervical mucopus in the two treatment groups at the initial and each of the three follow-up visits. Since some patients missed one or more follow-up visits, a "time to cure" could not be clearly defined for every patient. As shown in Fig. 1, the proportion of patients with mucopus decreased during the first month after therapy month, reached a minimum of 18% at 2 months in both groups, and increased at 3 months to 33% in the amoxicillin group and 23% in the doxycycline group. No significant difference between treatment groups was found in the proportion of women with mucopus at any of the visits.

The vast majority of persistent or recurrent mucopus after antimicrobial treatment could not be explained by the reisolation of *C. trachomatis, N. gonorrhoeae, U. urealyticum, M. hominis,* or *G. vaginalis* for follow-up. *C. trachomatis* was only isolated from four (27%) patients, and *N. gonorrhoeae* was isolated from none of the

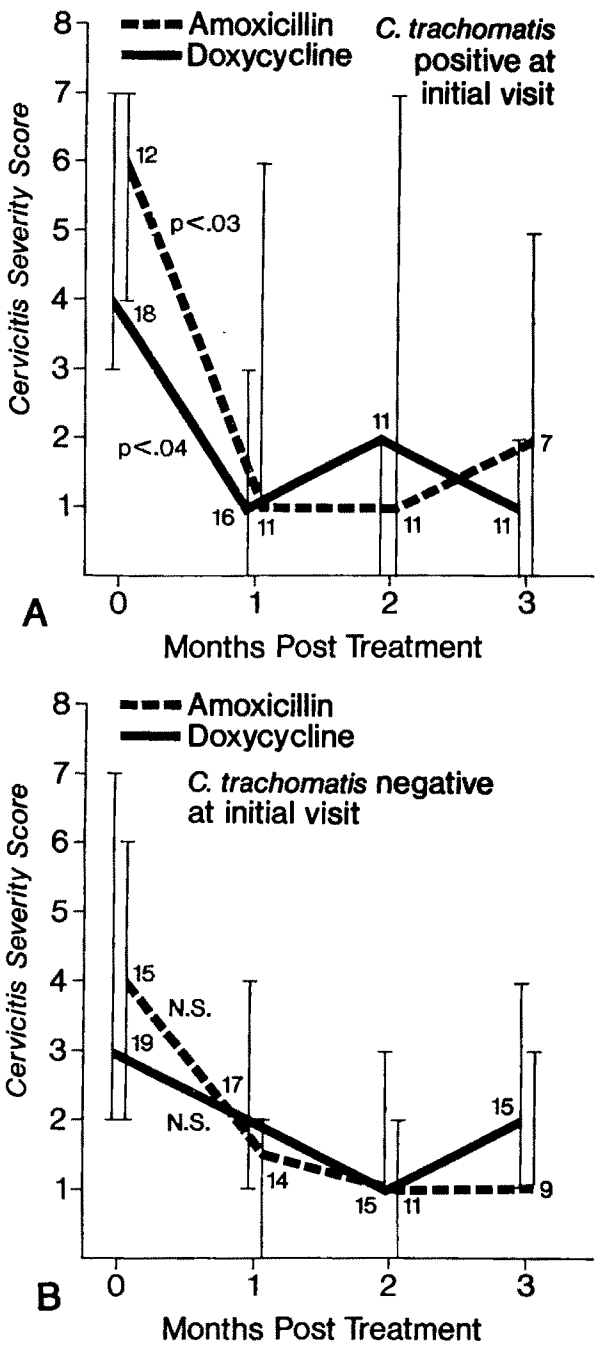

Fig. 3. Median cervicitis severity score with twenty-fifth and seventy-fifth percentiles before treatment and at 1, 2, and 3 months after starting treatment with doxycycline or amoxicillin among patients with positive (**A**) and negative (**B**) cervical culture for *C. trachomatis* (number indicates number of observations).

15 patients who had mucopus at the 2- or 3-month visit. The reisolation of none of the other organisms sought in this study correlated with mucopus on follow-up.

As shown in Fig. 2, the cervicitis severity score declined significantly after treatment in both treatment groups at 1 month ($p < 0.005$), and the improvement in severity score persisted throughout the follow-up period. The two antibiotic regimens had comparable effects on the cervicitis severity score of patients with *C. trachomatis*–positive (Fig. 3, *A*) and *C. trachomatis*–negative (Fig. 3, *B*) cervicitis. However, a statistically significant decrease in the cervicitis severity score only occurred among patients who were *C. trachomatis* positive. The follow-up severity score was not related to the isolation of *U. urealyticum*, *M. hominis*, and *G. vaginalis* on follow-up.

We also studied the effect of therapy on polymorphonuclear leukocyte counts observed in Gram-stained endocervical smears. As shown in Fig. 4, both doxycycline and amoxicillin therapy effectively lowered the polymorphonuclear leukocyte counts or the cervical mucus, and this effect persisted throughout the follow-up period. There was no relationship between the polymorphonuclear leukocyte count at follow-up and the initial diagnosis of chlamydial versus nonchlamydial mocupurulent cervicitis or the isolation of *U. urealyticum*, *M. hominis*, or *G. vaginalis* at follow-up.

Association of ectopy with persistent mucopus. Among women not initially infected with *C. trachomatis* or *N. gonorrhoeae*, oral contraceptives were used by nine (81%) of the 11 patients with persistent or recurrent mucopus and by three (25%) of 12 patients without persistent or recurrent mucopus ($p = 0.01$). This association was not seen among women who initially had *C. trachomatis* isolated. To further study factors that may be responsible for persistent mucopus, 24 patients with persistent mucopus and 20 patients without mucopus at each follow-up visit were further evaluated. The median areas of the ectocervix that showed ectopy ranged from 30% to 50% for those with persistent mucopus and from 10% to 20% for those without mucopus over the follow-up visits ($p = 0.01$), and more of them used oral contraceptives ($p = 0.04$) than women without mucopus on follow-up. Oral contraceptive use has been related to both ectopy and *C. trachomatis* isolation in other studies. Therefore a logistic regression analysis was performed with mucopus as the dependent variable and with ectopy, *U. urealyticum*, oral contraceptive use, and age as independent variables. Persistent mucopus remained associated with a greater area of ectopy ($p < 0.01$) after controlling for the other variables listed, whereas persistent mucopus was not significantly related to any of the other variables in this analysis.

Side effects. Side effects during the treatment were more common with doxycycline (46%) than with amoxicillin (26%) administration (Table III). However, side effects were generally mild and did not necessitate discontinuation of therapy in any patient.

Treatment of the male partner. Physical examinations were performed on 27 (42%) of the 64 potential male partners, including 17 (46%) partners of women

from the doxycycline group and 10 (37%) partners of women from the amoxicillin group. Of male partners, 15 had nongonococcal urethritis (one had *C. trachomatis*), one had both *C. trachomatis* and recurrent herpes, one had an asymptomatic *C. trachomatis* urethritis, and two other partners had gonococcal urethritis, one of whom also had *C. trachomatis*. Thus 19 (70%) of the 27 male partners of women with mucopurulent cervicitis had either clinical or culture evidence of urethritis. Persistence of endocervical mucopus was more common in women whose male partners had not received treatment (eight of 20) compared with women whose partners had received antibiotic treatment (five of 24), although the difference was not statistically significant.

Comment

Mucopurulent cervicitis is one of the most frequent genital infections among women. Approximately half of the women with mucopurulent cervicitis have had *C. trachomatis* or *N. gonorrhoeae* isolated from the cervix, and these organisms are well-established causes of the infection.[1, 2] *C. trachomatis* has been isolated four to five times more commonly than *N. gonorrhoeae* among women with mucopurulent cervicitis in our studies.[1, 2, 5, 6]

The recognition and proper treatment of endocervical infection by *C. trachomatis* or *N. gonorrhoeae* is considered important to prevent salpingitis and its sequelae. Tetracycline, erythromycin, sulfatrimethoprim, and to a lesser degree ampicillin have been successfully used to treat cervicitis caused by these two organisms.[13] However, previous treatment studies of cervicitis have left several issues unresolved. First, cure has been defined only by the eradication of *C. trachomatis* or *N. gonorrhoeae*. In men with nongonococcal urethritis, it has been conventional to demonstrate a reduction of clinical symptoms and urethral polymorphonuclear leukocytes as measures of therapeutic response. In contrast, the effects of antibiotic therapy on mucopus per se or on cervical mucus polymorphonuclear leukocytes have not been previously assessed in women either among those who initially had *C. trachomatis* or *N. gonorrhoeae* or among those without these two organisms. Second, long-term follow-up has not been used to study relapse or late recurrences. There is growing concern that conventional 1-week courses of therapy for chlamydial cervicitis may result in late recurrence that could persist for a prolonged time,[14, 15] causing ectopic pregnancy[16] or chronic salpingitis.[17] A comparison of short-term versus long-term tetracycline therapy, with an extended follow-up of perhaps 6 to 12 months, is required to further address the optimal duration of tetracycline therapy for cervical *C. trachomatis* infection.

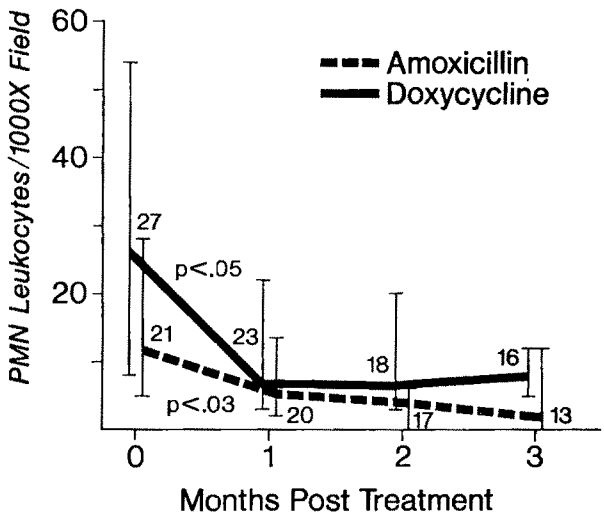

Fig. 4. Median number of polymorphonuclear leukocytes per ×1000 field in endocervical specimens with twenty-fifth and seventy-fifth percentiles obtained before treatment and 1, 2, and 3 months after treatment with doxycycline or amoxicillin (number indicates number of observations).

We chose amoxicillin to compare with doxycycline in this study because both are generally well tolerated and commonly used to treat cervicitis. Also, it was possible that differential therapy could provide clues to the cause of cervicitis among women without *C. trachomatis* or *N. gonorrhoeae*. Both antibiotics were expected to eradicate *N. gonorrhoeae* at the time the study was conducted in Seattle. Although both antibiotics have been reported to cure genital *C. trachomatis* infections, amoxicillin is less active than doxycycline against *C. trachomatis in vitro*,[13] and its use has been reported in relatively few women with *C. trachomatis*. Therefore we anticipated a lower efficacy for amoxicillin than doxycycline in the treatment of cervical mucopus, particularly among women with chlamydial cervicitis.

C. trachomatis was reisolated from two of 11 women treated with amoxicillin who were initially infected and from two of 15 women who were initially culture negative for the organism. Although these results are not significantly different from the results with doxycycline therapy, the power to detect a difference in the treat-

ment of *C. trachomatis* between the two antibiotics is low in this study. The failure rate in the amoxicillin group would have to have been 40% higher than that in the doxycycline group for the difference to be statistically significant (at a power of 80% and significance level of 5%), given the sample size and the *C. trachomatis* failure rate with doxycycline observed in this study. In a mouse model, amoxicillin has been more protective than ampicillin and oxytetracycline against intranasal *C. trachomatis*.[18] Amoxicillin, 750 mg, given three times daily for 7 or 10 days, eliminated *C. trachomatis* from the male urethra in previous small studies.[19, 20] However, there is continuing concern because low doses of amoxicillin have been less effective than other drugs for *C. trachomatis* infection in women.[21, 22] It has been further suggested that aminopenicillins may suppress *C. trachomatis* without killing the organism. Our results cannot definitively refute this notion, although *C. trachomatis* reisolation was infrequent for as long as 3 months after amoxicillin therapy. The effectiveness of amoxicillin and tetracycline against *C. trachomatis* needs to be compared in a larger study.

Since most women with mucopurulent cervicitis had neither *C. trachomatis* nor *N. gonorrhoeae,* it was of particular interest to find that the inflammatory response in this group diminished with antibiotic therapy as judged by mucopus, cervicitis severity score, or cervical polymorphonuclear leukocyte change after therapy. The cause of cervicitis among women without cervical infection by *N. gonorrhoeae* or *C. trachomatis* is not known, although the possibility remains that such cases actually have chlamydia or gonorrhea that was not detected by the methods used. In one study *U. urealyticum* was the only organism that significantly correlated with cervicitis after adjusting for *C. trachomatis*.[2] *U. urealyticum* has also been associated with non-chlamydial urethritis in men.[8] Persistent or recurrent mucopurulent cervicitis was not associated with the reisolation of *U. urealyticum* in this study, but too few patients were treated to exclude this possibility with certainty. Persistent or recurrent mucopurulent cervicitis was also not related to the reisolation of *M. hominis* or *G. vaginalis*. It is possible that persistent mucopus was caused by other antibiotic-sensitive organisms not identified in this study. However, the isolation of any organism from cervical cultures (except *N. gonorrhoeae* or *C. trachomatis*) must be interpreted with caution because of high contamination rates of these cultures with vaginal organisms. The natural history of nonchlamydial, nongonococcal mucopurulent cervicitis is uncertain, and it would be necessary to compare amoxicillin or doxycycline versus placebo to confirm conclusively the apparent effect of those antibiotics on the clinical course of this condition.

Larger studies are needed to determine whether the association between ectopy and mucopus among women with nonchlamydial, nongonococcal cervicitis represents an interaction between ectopy and an infectious agent or an independent effect of ectopy. It is possible that mucopus results from an inflammatory reaction caused by columnar cell contact with vaginal environment factors other than an infectious agent in patients without *C. trachomatis* or *N. gonorrhoeae*. Nevertheless, the weak association between the persistence of mucopus and no treatment of male partners lends support to the concept that even cervicitis not caused by *C. trachomatis* or *N. gonorrhoeae* may be attributed to an infectious agent. Histopathologic characteristics of cervicitis both before and after therapy may provide a better understanding of the causes of this important infection. More data are also required on the risk of women with nonchlamydial, nongonococcal cervicitis for upper genital tract infection.

Since many of the male sexual contacts of women with mucopurulent cervicitis had urethral infections, these data further support the Centers for Disease Control recommendations for male partner examination and treatment.[23] This article includes only nonpregnant women, and the findings are not necessarily applicable to pregnant women. Further study is required of the origin, treatment, and complications of mucopurulent cervicitis during pregnancy.

We thank Linda Cles and Judith Hale for performing microbiologic studies, the staff of Seattle–King County Sexually Transmitted Disease Clinic (H. Hunter Handsfield, MD, Director), and Laurie Johnson for manuscript preparation.

Right ventricular dysfunction in human fetal compromise

Juha Räsänen, MD, Pertti Kirkinen, MD, and Pentti Jouppila, MD
Oulu, Finland

Fetal M-mode echocardiography was performed in 13 pregnancies complicated by intrauterine distress. Absent end-diastolic blood velocity in the fetal descending aorta was documented by pulsed Doppler examinations. The right ventricular fractional shortening of these fetuses was decreased and the ratio of the right/left ventricular end-diastolic diameters was increased. The left ventricular size and myocardial contractility did not differ from normal pregnancy. These findings reveal that relative right ventricular heart dysfunction is associated with severe intrauterine distress. (Am J Obstet Gynecol 1989;161:136-40.)

Key words: Fetal heart, echocardiography, Doppler

Recent investigations with pulsed or continuous wave Doppler techniques have revealed that chronic fetal distress is commonly associated with hemodynamic changes in fetal and umbilical blood circulation. The diastolic flow in the fetal descending aorta and in the umbilical artery is decreased, whereas the fetal intracranial arterial diastolic flow components appear to be increased.[1-6] These changes are thought to reflect a redistribution of fetal cardiac output to the most vital fetal organs, but the pathophysiologic mechanisms are not known. The purpose of our study was to investigate fetal cardiac growth and myocardial function in conditions in which the fetus had developed a strongly abnormal blood flow pattern in connection with chronic intrauterine distress.

Material and methods

The study comprised 13 last-trimester pregnancies (pathologic pregnancy group) in which the Doppler velocity spectrum of the fetal descending thoracic aorta revealed that the end-diastolic blood velocity was decreased to 0 (no forward flow above the filter level during the last 2/10 of the heart cycle). In this group, severe preeclampsia was diagnosed in nine cases and cesarean section was later performed in seven cases because of a pathologic fetal heart rate pattern. In 11 cases, the birth weights of the newborns were < the 5th percentile, and in two cases, < the 10th percentile for normal pregnancies. The perinatal data of the material are presented in Table I.

Echocardiographic examination of these fetuses was made within 14 days (6.8 ± 5.6 days (mean ± SD), range of 0 to 14 days) before delivery, with a General Electric RT 3000 scanner with a 5 MHz sector probe. M-mode examination was done with a four-chamber view of the fetal heart by directing the M-mode level perpendicularly toward the interventricular septum at the level of the tips of the atrioventricular valves.[7,8] The end-systolic (ES) and end-diastolic (ED) diameters of the ventricles were recorded (from the endocardium to the interventricular septum) and the fractional shortenings of the ventricles were calculated [(ED − ES)/ED]. The mean circumferential shortenings of the ventricles, which allow the evaluation of the combined effect of fractional shortening with the duration of systole, were also calculated [(ED − ES)/ED × duration of systole]. The biventricular inner end-diastolic and end-systolic diameters (from endocardium to endocardium) were measured and the biventricular inner fractional change was calculated. The systolic period was restricted to the time when the atrioventricular valves were closed on the M-mode screen. Five correctly imaged consecutive heart cycles were analyzed and their mean values were used for further analysis. Heart growth was monitored by measuring the end-diastolic inner biventricular transversal diameter and inner end-diastolic transversal diameters of the ventricles. Biventricular, left and right ventricular fractional, and mean circumferential shortenings were calculated to assess the functional properties of the heart.

Immediately after the M-mode recording, the blood flow in the fetal descending thoracic aorta was examined with duplex pulsed Doppler equipment (Toshiba SAL-20, 3.5 MHz linear probe, and Pedof, 2 MHz probe, at a fixed 50-degree angle; 150 Hz filter).[3] Using the mean Doppler frequency shift, the time-averaged mean velocity, systolic peak velocity, end-diastolic velocity, pulsatility index [(peak velocity − end-diastolic velocity)/mean velocity during the cycle], and volumetric flow (ml/min) were calculated.[3] The flow parameters were based on registration of the mean blood velocity in the fetal descending thoracic aorta at

†$p < 0.05$.

intervals of 5.2 msec over 10 consecutive cycles. All measurements were made with the mother lying in a left recumbent position. Cardiotocography was normal in all cases on the same day when examined by the above mentioned ultrasonographic methods. The baseline of the fetal heart rate varied between 120 and 160 beats/min.

A group of 51 women with normal pregnancies (normal pregnancy group) was examined during the last trimester. There was no maternal history of diseases that predisposed the fetus to abnormal fetal growth in this group. Birth weights of these newborns were between the 10th and 90th percentiles of normal weight curves. Doppler and echocardiographic examinations were made in these cases in connection with routine ultrasonographic controls, corresponding to the examinations made in the pathologic cases. All of the control cases had continuous forward aortic blood flow over the whole of diastole.

Comparison of the means and linear regression coefficients was done by Student t test; $p < 0.05$ was selected as the level of significance.

Results

Table II shows the comparison of the echocardiographic findings between the two groups. Pregnancies with absent end-diastolic blood velocities of the fetal aortic Doppler examinations showed decreased values of right ventricular fractional and mean circumferential shortenings compared with normal pregnancies ($p < 0.0005$ for the means) whereas the left ventricular values remained normal. Correspondingly, the relationships between the right and left ventricular fractional and mean circumferential shortenings were decreased from those in normal pregnancy ($p < 0.0005$ for the means). Pregnancies with abnormal blood flow showed increased right/left relationships of the inner end-diastolic dimension of the cardiac ventricles ($p < 0.0005$ for the means).

Table III. Results of the fetal aortic Doppler examinations

	Normal pregnancy	*Pathologic pregnancy*
Total blood flow (ml/min)	725.1 ± 224.6	408.5 ± 167.6*
Pulsatility index	2.07 ± 0.44	3.33 ± 0.77*
Time-averaged mean velocity (cm/sec)	32.0 ± 5.28	20.1 ± 4.93*
Time-averaged peak velocity (cm/sec)	79.0 ± 14.2	63.1 ± 15.3*

All data represent mean ± SD.
*$p < 0.0005$.

The results of the flow measurements in the fetal descending aorta are presented in Table III. The pulsatility index was increased in the group with abnormal

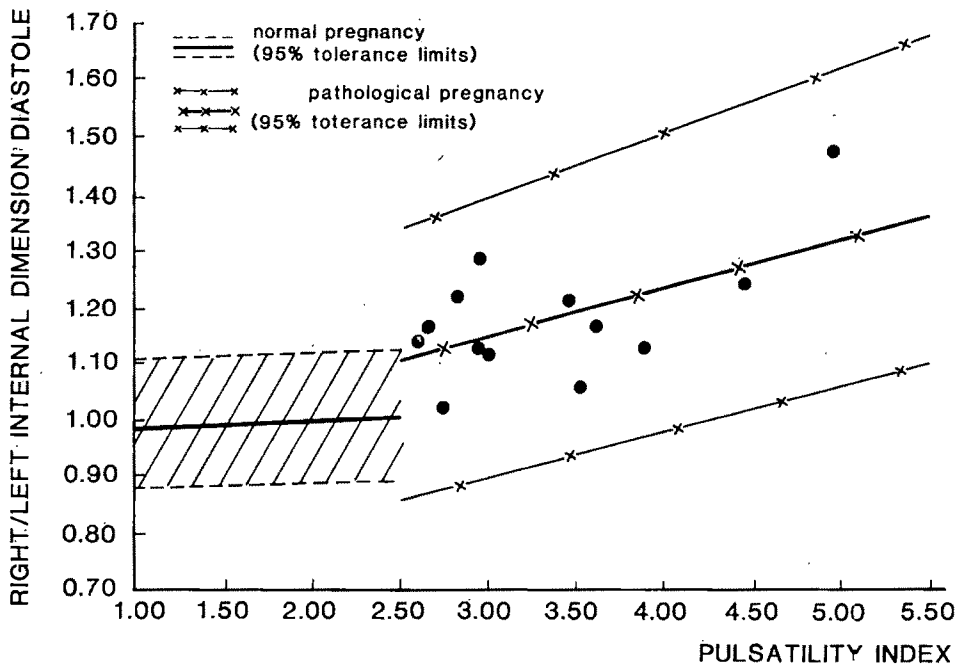

Fig. 1. Right/left ratio of ventricular inner end-diastolic dimensions plotted against corresponding pulsatility index in fetal descending thoracic aorta. •, Pathologic cases. Regression lines and 95% tolerance limits of both groups are presented. Significant difference between groups ($p < 0.02$).

flow ($p < 0.0005$ for the means) compared with normal pregnancies, whereas the blood velocities were decreased ($p < 0.0005$ for the means).

When the inner end-diastolic dimension of the right ventricle was plotted against the corresponding biparietal diameter, the cases with abnormal flow pattern showed increased right ventricular dimensions compared with normal cases ($p < 0.05$ for linear regression slopes). In 11 of the 13 abnormal cases, the right ventricular inner end-diastolic dimension was >50th percentile curve for normal fetuses. The left ventricular dimensions did not differ from those measured in the normal pregnancies.

In the normal pregnancies, the physiologic variation of the pulsatility index did not affect the right/left ratio of the ventricular inner end-diastolic dimensions. The cases with absent end-diastolic blood flow showed a significant increase in this ratio with increasing pulsatility index (Fig. 1; $p < 0.02$ for linear regression slopes). In fetuses with abnormal blood flow, the decrease in the blood velocities was associated with an increase in the right/left ratio of the ventricular inner end-diastolic dimensions compared with normal pregnancies (Fig. 2; $p < 0.03$ for linear regression slopes).

Comment

Our knowledge of human fetal myocardial function in intrauterine distress has largely been based on the evaluation of heart frequencies and their changes. In addition, some investigations by electrocardiography have been performed in cases of intrauterine distress.[9]

The characteristics of cardiac growth and myocardial function in uncomplicated pregnancies have been investigated by many authors.[7, 8] M-mode echocardiography has been accepted as a clinical tool for evaluation of suspected functional and structural disturbances of the fetal heart.[10-12] Recently much interest has been directed toward the use of continuous-wave and pulsed Doppler examination in obstetrics and the limitations and benefits of these techniques have been widely discussed.[13-15]

In all our cases with an abnormal aortic blood flow pattern, the cause was chronic placental insufficiency, primarily as a result of maternal vascular disease. This resulted in severe fetal growth retardation and intrauterine chronic distress. As commonly found with this type of intrauterine distress, these fetuses showed decreased velocities and increased waveform indexes in the Doppler measurements of descending aortic blood flow. It has been demonstrated that low mean blood velocity in the fetal descending aorta is associated with fetal hypoxia, hypercapnea, acidosis, and hyperlactemia. There have also been attempts to treat fetuses with intrauterine growth retardation by maternal oxygen therapy.[16, 17] In these conditions, the relationship between the systolic/diastolic flow components increases and a total block at end-diastole appears. On

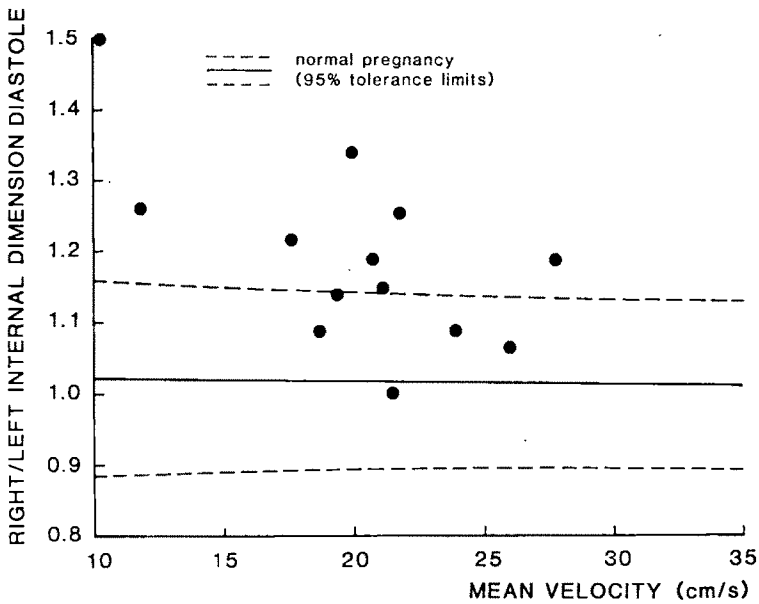

Fig. 2. Right/left ratio of ventricular inner end-diastolic dimensions plotted against time-averaged mean blood velocity in descending thoracic aorta. •, Pathologic cases. Significant difference between groups ($p < 0.03$).

the basis of this fact and the clinical outcome of our cases, we think that our cases represented severe intrauterine compromise, despite the fact that none of the fetuses died in utero.

Our cases demonstrated that the fetal heart reacts in such conditions by showing both an increased right/left relationship in ventricular dimensions and decreased contractility of the right ventricular myocardium. Left ventricular function appeared to remain normal. This may be a sign of fetal effort to maintain adequate cerebral and myocardial circulation as far as possible, since most of the left ventricular cardiac output is directed to these organs.[18] Thus relative right ventricular heart dysfunction of the fetus appears to develop. However, none of these cases had any signs of manifest decompensation such as ascites or edema. These fetal cardiac changes also seem to precede subsequent cardiotocographic abnormalities. DeVore[19] demonstrated right/left ventricular disproportion in the fetuses with abdominal circumferences ≤2 SD below the mean. Pulmonary hypertension was thought to be the cause of the right ventricular dilatation. It has been shown that most of the right ventricular cardiac output is ejected to the descending aorta via the pulmonary artery and the ductus arteriosus.[19] Thus it can be speculated that increased vascular resistance in the aorta could cause the dilatation of ductus arteriosus, pulmonary hypertension, and the changes in the right ventricular function. However, in our study we did not measure the transverse diameters of ductus arteriosus or pulmonary outflow tract.

In our previous study of hypertensive pregnancies, right-sided fetal cardiac ventricular dilatation was found to be associated with increased fetal vascular resistance in the descending aorta.[20] Our series showed that if vascular resistance is very severe, with loss of the end-diastolic aortic flow components, right ventricular myocardial contractility is also impaired.

We conclude that signs of increased peripheral vascular resistance in the fetal aorta in severe intrauterine distress seem to be connected with right ventricular dysfunction, without any evident disturbance of the left ventricle. However, these changes are very moderate with regard to clinical manifestations such as growth impairment and subsequent pathologic fetal heart rate patterns, which reflected the severity of fetal compromise in our material. This indicates that the human fetal heart has great functional reserves in chronic intrauterine distress.

Preterm and term fetal cardiac and movement responses to vibratory acoustic stimulation

Ronald L. Thomas, MD, Timothy R. B. Johnson, MD, Richard E. Besinger, MD, Deedra Rafkin, RN, Catharine Treanor, RN, and Donna Strobino, PhD

Baltimore, Maryland

To assess fetal response to vibratory acoustic stimulation, 24 preterm (group A; <36 weeks' gestation) and 30 term (group B; ≥36 weeks' gestation) pregnancies were studied. Study variables were perceived fetal movement, fetal heart rate, and fetal heart rate pattern. Observer- and patient-perceived fetal movement responses were noted in most cases but were slightly more common in term patients (group A: +fetal movement, patient 87.5%/observer 87.5%) group B: +fetal movement, patient 96.7%/observer 90%). Baseline changes in fetal heart rate (≥10 beats/min) were observed in 46% of preterm fetuses and 70% of term fetuses. Tachycardia (fetal heart rate >160 beats/min) was a common finding in both groups. In group A, tachycardia after vibratory acoustic stimulation persisted more than 1 minute in 29.2% and more than 5 minutes in 12.5% of patients. In group B tachycardia beyond 1 and 5 minutes was noted in 73.3% and 50% of patients, respectively. A significant shift to "awake" fetal heart rate patterns occurred in both groups; 29% to 79% was noted in group A ($p < 0.001$) and 46.7% to 90% in group B ($p < 0.001$). When vibratory acoustic stimulation was used, the high occurrence of increased baseline, tachycardia, and emergence of unusual fetal heart rate patterns must be recognized to adequately interpret fetal heart rate tracings. (Am J Obstet Gynecol 1989;161:141-5.)

Key words: Vibratory acoustic stimulation, fetal behavior

Observations on fetal response to external sound stimuli were first reported in the 1920s.[1,2] The concept of vibration/auditory interaction with the fetus was slowly rediscovered in the 1960s, 1970s, and 1980s. A number of recent studies[3-6] indicate that fetal acoustic stimulation has applicability in the evaluation of nonreactive nonstress tests. However, Gagnon et al.[7] showed evidence of alteration in fetal heart rate (FHR) and FHR patterns after vibratory acoustic stimulation in studying term gestations (36 to 40 weeks). Before the introduction of this technique into routine use at our facility, we conducted a pilot study to assess the effects of vibratory acoustic stimulation on FHR tracings and maternal and observer perceptions of fetal movements. A second concern was whether there was a differential effect of vibratory acoustic stimulation for term and preterm fetuses.

Material and methods

Fifty-four patients, including high-risk patients referred for nonstress testing (NST), contraction stress testing, or biophysical profiles, were studied. Each patient in the study was studied on only a single occasion. Because of previous work by Nijhuis et al.[8] suggesting development of organized fetal behavioral states at approximately 36 weeks, this gestation was chosen as the pivot point for our two groups. Study patients otherwise had routine and reassuring testing. A breakdown of referral indications is found in Table I.

Table I. Indications for referral

Indications for testing	*Preterm fetuses (%)*	*Term fetuses (%)*
IUGR	12.5	23.3
Hypertensive disease	25	13.3
Renal disease	8.3	0
Decreased movement	8.3	6.7
Diabetes	25	20
Bleeding hydramnios, lupus, Rh immunization, H/O loss, cardiac disease, miscellaneous	16.7	20
Postdates	0	20

IUGR, intrauterine growth retardation; *H/O*, history of.

Patients were selected from referrals to the Fetal Assessment Center over an 8-week period. Patient enrollment was based on scheduling load and the availability of additional monitoring time. Regardless of the indication for referral, all patients had an NST performed in standard fashion during the assessment. Five continuous minutes of monitoring were performed for

REM, Rapid eye movement.

each fetus before the application of vibratory acoustic stimulation. Stimulation of the fetuses was performed with an artificial larynx (Model 5-C; Western Electric). The instrument was applied to the fetal vertex, as identified by the Leopold maneuver, and two 2-second pulses of sound, which were separated by 30 seconds, were administered. Monitoring was continued on all patients until the FHR recorded had returned to the original baseline rate.

We measured FHR and FHR pattern before and after the vibratory acoustic stimulation using Hewlett-Packard fetal monitor Model HP 3040A. Fetal tachycardia was recorded if the FHR persisted above a rate of 160 beats/min for at least 1 minute; duration of tachycardia was also recorded. Definitions for FHR patterns were those described by Nijhuis et al.[8] and Martin[9] and appear in Table II. Patterns were categorized according to the criteria most clearly met by the tracing in the 5 minutes before and the 5 minutes immediately after acoustic stimulation.

In evaluating FHR patterns, we were interested in shifts that occurred from those patterns typically recorded in term fetuses (≥36 weeks) with sleep and awake states. Table II outlines the definitions and tracings of four FHR patterns used in our study and their association with "sleep" and "awake" states. FHR patterns do not form part of a defined behavioral state before 36 weeks; nonetheless, induced changes are observed.

Maternal and observer perceptions of fetal movements after vibratory acoustic stimulation were also recorded. Maternal perception of fetal movement was recorded as positive if the patient noted an immediate and obvious fetal kick or movement within 10 seconds of the stimulus. Observer perception of movement was recorded as positive if a definite sudden movement was palpated by a hand placed on the uterine fundus. Fetal movement was recorded as positive if movement was felt after either of the two sequential stimulations. The χ^2 test for independence was used to compare differences in the percentage of fetuses with tachycardia with those with a given heart rate pattern. The analysis was performed separately for term and preterm groups. Small numbers did not permit age and parity comparisons.

Results

The gestational ages in group A ranged from 26.9 weeks to 35.9 weeks, with a mean of 32.9 weeks. In group B fetuses ranged in gestational age from 36 weeks to 42.7 weeks, with a mean of 38.9 weeks. In response to vibratory acoustic stimulation, 19 (79.2%) of the preterm fetuses showed some increase in FHR, with an average rise of 16 beats/min. Eleven of 24

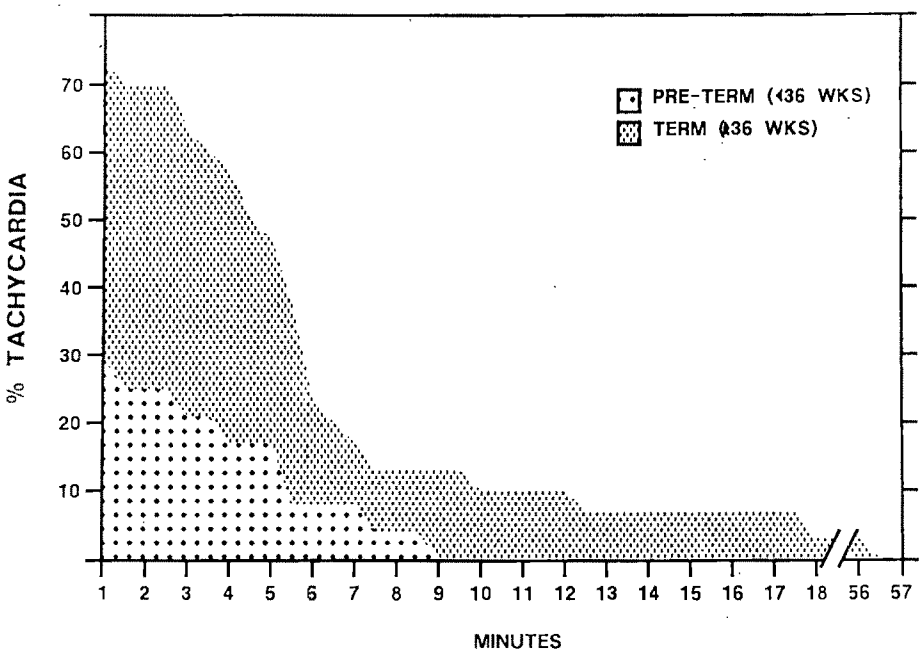

Fig. 1. Preterm and term tachycardiac responses to vibratory acoustic stimulation and their duration.

Table III. Data breakdown in study groups

	Group A	*Group B*	*Significance*
Gestational age range (wk)	26^{+6}-35^{+6}	36-42^{+5}	
Gestational age (mean ± 1 SD) (wk)	32.9 ± 2.2	38.9 ± 2.0	
Patient-perceived movement with VAS (%)	(87.5)	(96.7)	NS
Observer-perceived movement with VAS (%)	(87.5)	(90) $p < 0.05$	NS
Mean increase in FHR baseline with VAS ± 1 SD (beats/min)	12.3 ± 9.5	16.2 ± 10.6	NS
Baseline increases of 10 beats/min above baseline (%)	46	70	
Tachycardia ≥ min (%)	29.2	73.3	$p < 0.0001$
Tachycardia ≥ 5 min (%)	12.5	50	$p < 0.001$

VAS, Vibratory acoustic stimulation.

(46%) preterm fetuses had a rise in FHR of more than 10 beats/min. A decrease in FHR was noted in one case. Among term fetuses, 26 of 30 (86.7%) fetuses showed an increase in FHR in response to acoustic stimulation; the mean rise was 16.9 beats/min. The increase in FHR in 21 of 30 infants was more than 10 beats/min (70%). Again, one fetus showed a decrease in FHR in response to vibratory acoustic stimulation.

Among the preterm infants, seven of 24 (29.2%) fetuses had tachycardia lasting for at least 1 minute, and three (12.5%) had more than 5 minutes of tachycardia. In term fetuses, at least 1 minute of tachycardia was found in 22 of 30 fetuses (73.3%) and persisted for more than 5 minutes in 15 fetuses (50%) (Table III). The pattern of persisting tachycardia is seen in Fig. 1.

Figs. 2 and 3 demonstrate shifts in FHR patterns before and after vibratory acoustic stimulation for preterm and term fetuses, respectively. In preterm fetuses there was a significant shift from "sleep" patterns (FHR patterns A and B) to "awake" patterns (FHR patterns C and D). Before acoustic stimulation, 20% of fetuses in the preterm group had either FHR pattern C or D. The percentage increased markedly to 79% after vibratory acoustic stimulation. FHR patterns C and D were more commonly identified in term fetuses, but nonetheless, there was a significant shift in fetuses not already exhibiting one of the two "awake" patterns, from 46.7% to 90% after vibratory acoustic stimulation.

No difference was noted in fetal movements as perceived by an observer from those perceived by the pa-

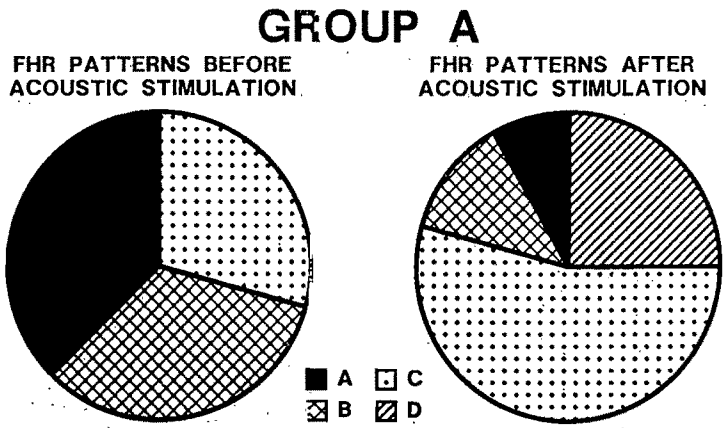

Fig. 2. FHR patterns in preterm fetuses before (FHR pattern A, 37.5%; FHR pattern B, 33.3%; FHR pattern C, 29.2%) and after vibratory acoustic stimulation (FHR pattern A, 8.3%; FHR pattern B, 12.5%; FHR pattern C, 54.2%; FHR pattern D, 25%).

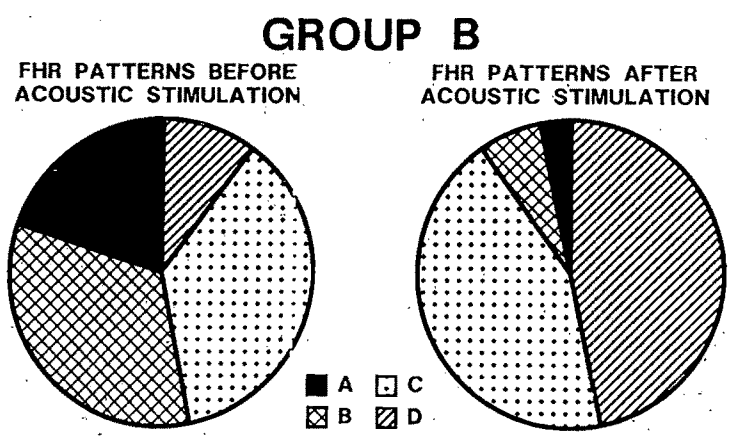

Fig. 3. FHR patterns in term fetuses before (FHR pattern A, 20%; FHR pattern B, 33.3%; FHR pattern C, 36.7%; FHR pattern D, 10%) and after vibratory acoustic stimulation (FHR pattern A, 3.3%; FHR pattern B, 6.7%; FHR pattern C, 43.3%; FHR pattern D, 46.7%).

tient. Only rarely was there a discordance noted in perception. In the term group the patient more commonly perceived fetal movement (96.7% versus 90%, $p < 0.05$) than the observer. Perception of movement was slightly more common in term fetuses.

Comment

Significant changes in baseline FHR have been noted after vibratory acoustic stimulation. The changes in baseline were as common in group A as in group B. This is contrary to the lack of baseline change reported by Gagnon et al.[10] (30 to 42 weeks). Observed tachycardia probably does not represent stress but a physiologic response to a nonphysiologic stimulus, vibratory acoustic stimulation. The tachycardia raises theoretic concerns that the severely compromised fetus might be further compromised by vibratory acoustic stimulation. Also, since "tachycardia" has been reported as an ominous sign by several investigators,[11, 12] its occurrence after vibratory acoustic stimulation without other complicating factors needs to be recognized as not being prognostically important. It also appears from our data that the FHR changes reported in term fetuses also occur in preterm fetuses. This implies that these changes may be independent of behavioral states that do not form before approximately 36 weeks. These findings confirm those previously reported by Gagnon et al.[7]

The shifts noted in FHR patterns, particularly from FHR pattern A to B, C, and D may explain the observations that we and others[3, 5] have noted of a decrease in nonreactive NSTs with vibratory acoustic stimulation applications. Baseline rate increase and tachycardia are also common responses. Vibratory acoustic stimulation during antepartum fetal testing has become popular during the past decade. Preliminary work shows it to

be efficacious and cost-effective. Thus far, antepartum vibratory acoustic stimulation has been limited in application to its influences on the NST. The physiologic mechanism of fetal response has not been delineated, but it is theorized that there may be an alteration in fetal behavioral state in response to vibratory acoustic stimulation.

Previous studies reported by Nijhuis et al.[8] have detailed behavioral studies in neonates and term and preterm fetuses. Their work reports organized behavioral states existing at 36 weeks; individual parameters of these states, such as FHR patterns, although not states, are definable before 36 weeks' gestation. Nevertheless, these patterns may be concordant with associated behavioral states in the term fetus and neonate (see Table II). Transitional patterns are found as shifts from one pattern to another occur. A computer-based analysis of FHR patterns has shown that a good correlation with individual visual classification exists.[13] In the normal fetus (and neonate), most of the time is spent in FHR patterns A and B. These patterns (at 36 weeks and beyond) are associated with sleep (nonrapid eye movement and rapid eye movement), and although FHR accelerations occur with movement in all states, they are less frequent during sleep. Gagnon et al.[7] hypothesize that the changes seen with vibratory acoustic stimulation, such as in antepartum fetal monitoring, may be a reflection of state change in the fetus.

There is an obvious fetal movement/startle response with vibratory acoustic stimulation. Ultrasonography has been used to document fetal "startle" responses to vibratory acoustic stimulation.[14] Given the high proportion of cases in which the patient and observer perceived nearly immediate response recognition, ultrasound documentation may be superfluous. This response in and of itself may provide a rapid assessment of gross fetal compromise. Westgren et al.[15] have recently reported on a series of patients to correlate fetal movement response with a reactive NST and show a sensitivity of 100%. There are also significant alterations in FHR pattern with vibratory acoustic stimulation including "tachycardia," which may be prolonged. Caution must be taken before universal application of this nonphysiologic stimulus. Whether the development of tachycardia or FHR pattern C or D is equivalent to a "reactive NST" is presently not known. Furthermore, whether perception of fetal movement in response to vibratory acoustic stimulation is equivalent to a reactive NST is also unknown. More detailed study is needed to better understand the highly unusual FHR responses that occur with vibratory acoustic stimulation. Application of non-FHR observations may provide additional tools to assess the fetus at risk for in utero compromise.

Effect of physician characteristics on the cesarean birth rate

Gertrud S. Berkowitz, PhD,[a] Gale S. Fiarman, MD,[b] Michael A. Mojica, MD,[b] Jay Bauman, MD,[c] and Roberta Haynes de Regt, MD[d]
New York and Elmhurst, New York

The rising cesarean birth rate has become of increasing concern to the obstetric profession and the public. There is a general consensus that the major obstetric indications responsible for the rising rate are dystocia, fetal distress, breech presentation, and previous cesarean delivery. However, the role of sociologic or nonmedical factors has not been established. This retrospective study examines the effect of the physician's age, experience, gender, and practice setting (solo versus group practice) on the cesarean birth rate. The analysis is based on 6327 private deliveries performed by 48 attending obstetrician/gynecologists at a New York City Hospital from January 1983 through December 1985. Although no significant differences were found according to the gender or practice setting of the physicians, older, more experienced physicians performed significantly fewer cesarean sections for dystocia and a higher percentage of forceps deliveries and breech extractions. These results suggest that physician characteristics may affect the type of delivery that is performed. (Am J Obstet Gynecol 1989;161:146-9.)

Key words: Cesarean birth rate, forceps deliveries, physican characteristics

The cesarean birth rate in the United States has increased from 5.5% in 1970 to 22.7% in 1985.[1] This dramatic rise in the incidence of cesarean sections has caused concern both in the obstetric profession and the general public.[2, 3] There is general agreement that the most important obstetric indications responsible for this increase are dystocia, breech presentation, fetal distress, and previous cesarean delivery.[1-3] The underlying reasons behind the changing incidence and indications cannot be readily documented, but several factors have been suggested, including the relative safety of cesarean births for the mother and fetus, improved prognosis of low birth weight infants, increased proportions of nulliparous and older mothers, higher proportions of deliveries performed by obstetricians as opposed to general practitioners, improved third-party payment, and fear of malpractice suits.[2]

Variations in rates by geographic region and type and size of hospital have also been noted. The highest cesarean delivery rates have been recorded in the Northeast, teaching hospitals, and hospitals of 500 beds or more.[4, 5] In addition, private patients have been found to be more likely to undergo cesarean sections than their service[6] or health maintenance organization[7] counterparts. Although these data do much to emphasize the role of nonmedical factors, little is known about the influence of physician characteristics on the cesarean birth rate. The purpose of this article is to examine how physician age, experience, gender, and practice setting affect the clinical decision to perform a cesarean section at one New York City hospital.

Material and methods

A total of 10,461 deliveries were performed at the Mount Sinai Hospital in New York City between January 1983 and December 1985. Private patients represented 63% of the deliveries, and clinic patients accounted for 37% of the deliveries. The overall cesarean birth rate for this period was 21.8%, which is comparable with that of the Northeast United States.[5] The cesarean rate was higher for private patients (24.0%) than for clinic patients (18.2%).

To reduce the number of factors that might influence the cesarean birth rate, this study was limited to deliveries of private patients. Excluded from the 54 physicians who delivered private patients were four full-time attending physicians who managed only high-risk patients and two physicians who shared the same surname and who were not consistently identified in the delivery log book. The remaining 48 physicians constituted the study population and accounted for 6327 deliveries during the study period. The great majority of private patients were white, married, over the age of 25 years, had some college education, and used third-party insurance payment.

The data were obtained from a delivery log book. The information abstracted comprised the primary physician responsible for the delivery, the mode of delivery, and the stated indication for each cesarean sec-

Table I. Description of physician characteristics

Characteristic	*No.*	*%*	*Mean age ± SD*	*Mean yr of experience ± SD*
Male	37	77.1	49.4 ± 11.2*	18.5 ± 11.5*
Female	11	22.9	34.6 ± 4.3	3.3 ± 2.8
Solo	23	47.9	49.6 ± 12.7*	18.0 ± 13.8
Group	25	52.1	42.3 ± 9.7	12.2 ± 9.7
Total	48	100.0	46.0 ± 11.9	15.0 ± 12.1

*$p < 0.05$.

tion. Indications for cesarean sections were classified as dystocia, fetal distress, breech, repeat or "other." The term dystocia included both failure to progress and cephalopelvic disproportion. The category of "other" included mostly herpes, placenta previa, placental abruption, prematurity, and previous uterine surgery. When multiple indications were present, the model derived by Anderson and Lomas[8] was used to determine the primary indication. Those cesarean sections without clear indications (approximately 10%) were cross-referenced with discharge summaries available in the Mount Sinai Hospital Department of Medical Records.

Data on the physicians' characteristics included gender, date of birth, residency program, date of completion of residency program, and whether the physician was in a solo or group practice. Age was calculated in years as of July 1984, the midpoint of the study period. Experience was defined as the number of years from the completion of an Obstetrics and Gynecology residency program to the midpoint of the study period. The influence of place of residency was not assessed, since 70.8% of the physicians studied were trained at Mount Sinai Hospital and an additional 12.5% trained at other teaching institutions in New York City.

The cesarean birth rate was defined as the percentage of total deliveries that were performed by cesarean section. The primary cesarean birth rate was expressed as the percentage of total deliveries, which represented cesearean sections for an indication other than repeat sections. Operative vaginal delivery rate was defined as the percentage of all deliveries that used forceps or were breech extractions. Overall operative delivery rate was defined as the percentage of total deliveries that used forceps, were breech extractions, or required cesarean sections. Finally, the four major indications for cesarean section were analyzed as a percentage of total cesarean sections.

All rates were based on the 48 physicians as the units of analysis. Student t test and the Pearson product-moment correlation coefficient were used for statistical evaluation. Where appropriate, nonparametric analysis with Wilcoxon rank sum test and Spearman's rank correlation coefficient was also performed. The level of significance was selected as $p = 0.05$. Computations were performed by the CLINFO statistical package at the Mount Sinai Hospital Department of Biomathematical Sciences.

Results

Table I describes the characteristics of the 48 study physicians. Thirty-seven (77.1%) of the physicians were men and 11 (22.9%) were women. The male physicians were significantly older and more experienced than the female physicians. About half (52.1%) of all physicians participated in group practices. Those in solo practice were significantly older and slightly more experienced than those in group practices.

The 6327 deliveries performed by the 48 physicians during 1983 to 1985 are summarized in Table II. The cesarean birth rate was 23.7% with dystocia (27.8%) as the most common indication, followed by repeat sections (24.8%), fetal distress (13.8%), and breech presentations (13.1%). The indications for the remaining 20.5% of the cesarean sections were classified as "other." The primary cesarean section rate was 17.8% and the operative vaginal delivery rate was 24.7%.

Physician age did not correlate significantly with the cesarean section rate ($r = 0.06$), the primary cesarean section rate ($r = 0.07$), or the percentage of cesarean sections performed for repeat ($r = 0.18$), breech ($r =$

Table III. Operative delivery rates according to physician's gender

Fetal distress	16.1	16.1	14.0	6.1	0.78

*Percentage of cesarean deliveries.

0.04), or fetal distress ($r = 0.06$). A significant negative correlation was found between age and the percentage of cesarean sections performed for dystocia ($r = -0.38$; $p = 0.008$).The operative vaginal delivery rate increased significantly with age ($r = 0.43$; $p = 0.002$). The overall operative delivery rate was also positively correlated with age ($r = 0.46$; $p = 0.001$). Similar results were obtained when assessing the effect of years of experience, since age and years of experience were highly correlated ($r = 0.90$; $p = 0.0001$). Reanalysis of these variables with Spearman's rank correlation test did not alter the results.

As shown in Table III, male physicians tended to have slightly higher operative delivery rates and a lower proportion of cesarean sections for dystocia than did female physicians, but none of the comparisons were statistically significant. With respect to practice setting (Table IV), there was some suggestion that physicians in solo practice had higher primary cesarean section rates than those in group practice. However, no significant associations were observed between overall operative delivery rates and solo versus group practice.

Comment

Although no overall associations could be found between specific physician characteristics and cesarean section rates, physician's age and experience were positively correlated with higher operative vaginal delivery rates and negatively related tc the percentage of cesarean sections for dystocia. Age and experience were highly correlated, and individual effects could not be separated.

Increasing age and experience are two physician characteristics that may simply represent differences in management based on techniques acquired in training at a time when forceps and breech extraction deliveries were more commonly performed. Since more cesarean sections are being performed today for breech presentations or as an alternative to a difficult vaginal delivery, residents in training or younger physicians have not been exposed to as many operative vaginal techniques as their senior counterparts.[3]

Other physician characteristics that were examined included gender and practice setting. Gender was not found to be statistically associated with any of the operative delivery rates, although male physicians were both older and more experienced. There was some suggestion that male physicians had a higher operative delivery rate and a lower rate of cesarean sections performed for dystocia. The relatively small sample size, particularly of female physicians, may account for the lack of significant findings. Further study is warranted in the future when more women will have completed training programs.

Similarly, no significant effect of practice environment could be delineated. Since solo practitioners

tended to have a higher primary cesarean section rate than group practitioners, it is possible that significant differences would be obtained with a larger sample size. Nevertheless, the absolute differences in operative rates for physicians in solo as opposed to group practices were small. Although solo practitioners are probably more subject to the pressures of time constraints and fatigue than those in group practice, there is no convincing evidence that the "convenience factor" plays an important role in cesarean birth rates. Evans et al.[9] and Fraser et al.[10] concluded that physician convenience may have influenced the timing of "nonacute" or dystocia cesarean sections, but Phillips et al.[11] found no difference in the distribution of nonelective cesarean section indications between weekends and weekdays. Carpenter et al.[12] found lower overall cesarean rates and lower dystocia cesarean rates if physicians shared night call with at least two other colleagues. However, payment differential between vaginal and cesarean delivery, average annual deliveries per practice, and in contrast to our study, number of years since training were not correlated with cesarean rates.

The effect of the medicolegal climate on individual physicians and their operative rates is difficult to assess. If frustration or fear of litigation can affect the decision of *whether* to practice,[13] then it can be postulated to affect the decision of *how* to practice. Nevertheless, in the study by Carpenter et al.[12] physicians with a recent threat of a malpractice suit had lower cesarean rates than those who had not recently experienced medical liability.

Other physician characteristics that might potentially influence operative rates that deserve study include personality, fund of knowledge, and previous poor perinatal outcomes. The effect of the patient's risk status on operative delivery rates also needs to be considered in future studies.

What can be done to lower operative rates without sacrificing perinatal morbidity? Wennberg[14] found that feedback from professional committees could reduce variation in operative rates caused by physician characteristics. Porreco[15] and O'Driscoll and Foley[16] have shown that institutional standardization of clinical policy can decrease the cesarean birth rate without compromising favorable perinatal mortality rates. Other recommendations to reduce the effects of physician characteristics on perinatal decision-making include mandatory second-opinion consultation before surgery, the institution of peer-review panels, and physician continuing education programs. Since this study examined physician characteristics and operative rates in a fairly homogeneous study population, other centers could evaluate physicians with more diverse training backgrounds and varied physician characteristics.

This investigation was undertaken as partial fulfillment of the clerkship requirement in Community Medicine while Gale S. Fiarman and Michael H. Mojica were third-year students at Mount Sinai School of Medicine.

Court-ordered cesarean section: An analysis of ethical concerns in compelling cases

Thomas E. Elkins, MD,[a] H. Frank Andersen, MD,[a] Mel Barclay, MD,[a] Tina Mason, MD,[a] Noelle Bowdler, MD,[a] and Garland Anderson, MD[b]

Ann Arbor, Michigan, and Memphis, Tennessee

Two previously unreported cases are presented in which court-ordered cesarean sections were considered appropriate by physicians. An analysis of the factors that compel physicians to deem court-ordered intervention appropriate is presented. When the significance of a third-trimester fetal death or a lifetime physical or mental disability is balanced against the demand to uphold maternal autonomy at all costs, the recognized ethical principles of beneficence, nonmaleficence, justice, obstetric contract keeping, and acting in the patients' best interests combine, in rare situations, to override concerns for individual maternal autonomy and justify court-ordered intervention. (Am J Obstet Gynecol 1989;161:150-4.)

Key words: Ethics, cesarean section, medical-legal, fetal death

The following case presentations represent previously unreported situations in which court-ordered cesarean sections were considered appropriate by physicians. They are actual accounts of patient care dilemmas in which court orders were considered or obtained. In these situations, multiple coercive/pleading arguments were presented to the patients, and lengthy deliberations were made before court orders were sought. An analysis of the factors that compel physicians to deem court-ordered intervention appropriate in these instances follows the case presentations.

Case reports

Case No. 1. In 1975 a 27-year-old, unmarried, white woman, gravida 1, para 0, was first seen at Planned Parenthood where she requested pregnancy termination. Because of her advanced gestation, approximately 30 to 34 weeks, she was advised that pregnancy termination was not possible. However, because she had a blood pressure of 180/110, she was immediately transferred to a tertiary care hospital. At the time of admission, the patient was noted to have similar blood pressures, along with other findings suggestive of severe preeclampsia. In the hospital she again asked that an abortion be performed. She was initially managed with bed rest; however, the following morning a decision was made to induce labor.

Received for publication October 17, 1988; accepted January 11, 1989.

Reprint rqeuests: Thomas E. Elkins, MD, Department of Obstetrics and Gynecology, University of Michigan Medical Center, 1500 E. Medical Center Dr., D2234 MPB, Box 0718, Ann Arbor, MI 48109-0718.

Cervical dilatation was 2 to 3 cm. Her mentation and affect were appropriate. An intravenous infusion of magnesium sulfate was started. External fetal monitoring demonstrated spontaneous rhythmic uterine activity with late decelerations. Membranes were ruptured artificially and internal fetal monitors were placed. Internal monitoring confirmed loss of baseline variability and moderate-to-severe late decelerations. A scalp pH was performed and was 7.09. The patient agreed to these medical procedures without objections.

The patient was advised that there was fetal distress and that she should be delivered immediately by cesarean section. She refused the operation, stating that she did not want the baby. Despite repeated requests from house officers, staff, and nursing personnel, the patient continued to refuse surgical delivery. Oxytocin augmentation was begun in the hope that a vaginal delivery could be accomplished. During this time the fetal heart rate tracing continued to deteriorate, showing severe late decelerations, absent variability, and prolonged episodes of bradycardia. A sister of the patient, who was located by telephone, came to the hospital, and attempted to convince the patient that a surgical delivery was needed.

Two and one-half hours after the first scalp pH, a second scalp pH was reported was 6.71. Labor continued. Finally, a stillborn female infant, weighing 2140 gm, was delivered spontaneously.

After the patient's initial refusal of the cesarean delivery, the hospital attorney was contacted. The attorney spoke with three local judges, each of whom refused to hear the case.

Post partum the patient commented that she felt the staff had disapproved of her refusal of cesarean section for fetal indications. Although the hypertension and proteinuria had not resolved, she signed out of the hospital on the third postpartum day against medical advice.

Case 2. A 24-year-old, nonindigent, white woman, gravida 1, para 0, was admitted at 34 weeks' gestation dilated 2 to 3 cm with ruptured membranes and frequent contractions. The patient had left another hospital against medical advice because a cesarean section was recommended. She had hypertension (blood pressure 160/110), 3+ edema, and 3+ proteinuria. Electronic fetal monitoring showed absent variability, persistent late decelerations, and intermittent episodes of severe bradycardia. Heavy meconium was noted. The patient again refused all initial recommendations for cesarean section. She appeared almost noncommunicative, with a flat affect, and was unwilling to discuss her decision. Her mother was contacted and said that the patient had appeared very depressed and withdrawn for a couple of weeks and that the mother was also unable to communicate with her. The patient allowed fetal scalp pH determinations to be done. The first showed a pH of 7.10. A second scalp pH, performed an hour later, was 6.96. Even with these indications of fetal distress, the patient would not agree to cesarean section. After a total of 4 hours of pleading, a juvenile court judge was contacted directly by the attending obstetrician and a court order was obtained to proceed with cesarean section. The patient remained uncooperative.

The patient was forcefully restrained while general anesthesia was induced. A cesarean section was then performed, which resulted in the delivery of a 4-pound male infant with Apgar scores of 2 at 1 minute, 5 at 5 minutes, and 7 at 10 minutes. The operation was otherwise uncomplicated, as was the mother's postoperative course. The infant initially suffered from seizures but stabilized within 48 hours and did well thereafter.

Postpartum the patient requested custody of her infant and indicated that she understood in retrospect that surgery had been necessary. She has been followed closely by social service agencies and appears to be functioning appropriately in relation to her infant. At 1 year of age, the infant appears developmentally within the normal range.

Comment

A number of articles have recently appeared in opposition to obstetric intervention of any kind without maternal consent and especially to court-ordered cesarean section for fetal benefit when maternal consent is not obtained.[1-3] Several arguments have been presented to justify such opposition to court-mandated obstetric management. Individual patient situations have revealed errors in physicians' clinical assessments, resulting in the pursuit of court orders for intervention that appeared unnecessary in retrospect.[6, 7] Other authors have emphasized respect for the principles of bodily integrity, privacy, and autonomy that are valued as near absolutes in our society.[8] The right of competent adults to refuse medical therapy of any kind is also noted.[9]

Others have proposed that the fetus is the property of the mother who should have the sole right of decision-making in any obstetric question.[10] This is consistent with literature that states that any consideration of fetal rights is philosophically nonjustifiable.[11]

General agreement exists that extensive seeking of court opinions to force women to comply with nonemergent medical care is unwarranted. Many fear that opening the door to forced cesarean sections will encourage mandated behavior on the part of pregnant women in general and that such forced interventions could have a negative effect on maternal participation in prenatal and intrapartum care.[12]

The Committee on Bioethics of the American College of Obstetricians and Gynecologists has recently stated: The use of courts to resolve these conflicts is almost never warranted . . . obstetricians should refrain from performing procedures that are unwanted by a pregnant woman.[13] Even the strength of this statement in its opposition to forced obstetric intervention has been criticized by some, who object to the word "almost" in this sentence.

Although the authors concur in general with these concerns against court-ordered intervention and the opinion of the American College of Obstetricians and Gynecologists Bioethics Committee, it is their belief that there are rare circumstances in which court-ordered intervention on behalf of the third-trimester fetus is warranted. An analysis of the patient management situations in this article gives some rationale for the reluctance of many obstetricians to condemn court-ordered intervention in all situations.

Certain standard arguments in maternal-fetal conflicts have not been helpful to physicians, including relying on legal arguments and reasoning with false analogies. Many physicians prefer to rely on prior court decisions or federal or state legislation as guides to medical decision-making in an era of concern for malpractice liability. However, in the particular problem of maternal-fetal conflict, a reliance on the law as a guide to medical decision-making is not helpful. Case law and statutes that have established a doctrine of informed consent in our society would appear to support any consenting adult's right to refuse medical treatment.[14] However, multiple court decisions since *Roe v Wade*[15] have emphasized societal concern for the well-being of the viable third-trimester fetus. Case precedents show that the fetus has some rights of well-being in pregnancy for which damages might later be sought,[16] a right of inheritance that may legally be pursued after birth, and the legal status of personhood in some narrowly worded decisions.[17] In practical terms, physicians who seek to practice defensive medicine realize very quickly that they may be held liable for their decision to treat a patient against her will in the third trimester

or for a decision to agree to nontreatment that then leads to either death of a third-trimester fetus or birth of a severely handicapped newborn.[18] Therefore those who suggest a decision-making model that is protective for the physician in a legal sense offer no guidance in the area of maternal-fetal conflict.

Second, arguments for and against intervention have been based on equating the maternal-fetal relationship with other familial relationships. Some have argued that the maternal-fetal relationship is analogous to a parent-child relationship and that any maternal action that brings harm to the third-trimester fetus constitutes child abuse or neglect.[3] In contradistinction, others have tried to equate maternal-fetal concerns with those of siblings, one of whom needs a bone marrow transplant. Since society has not forced one sibling to undergo minor surgery for bone marrow or organ transplantation to help the other sibling, they reason that gestational mothers should not be compelled to aid the third-trimester fetus.[10] Without undue discussion, it may simply be stated that neither of these situations may be equated to the extreme interdependency of the mother and fetus in the third trimester when the life of both parties is dependent on the medical condition of the other. Therefore in extreme situations obstetricians may be faced with difficult decisions in which they must weigh numerous concerns involving both mother and fetus.

Although case No. 1 occurred before emergency court-ordered interventions had been reported, the similarities in these two cases allow a single analysis of the ethical priorities of the physicians involved in both cases.

(a) In both cases, there was no question that fetal distress existed and that fetal death or severe brain damage to the newborn would occur without surgical intervention. Therefore in this instance, erroneous clinical judgment, cannot be considered a factor that would speak against pursuit of court-ordered intervention.

(b) Oftentimes in cases of maternal-fetal conflict, there is reason to pursue court-ordered intervention for the physical well-being of both mother and fetus. This is true in cases of central placenta previa or gross fetal pelvic disproportion in which delivery of a healthy fetus by cesarean section is only one reason to pursue a cesarean section, since attempted vaginal delivery might also result in severe physical harm and even death to the mother. In the cases presented here, expedient delivery was indicated in each situation for severe preeclampsia. However, in both of these cases, cesarean section was sought primarily for fetal benefit because of the presence of fetal distress.

(c) In neither of the cases presented here was there a prolonged physician-patient relationship at the referral hospital where delivery occurred. Neither patient had attended prenatal care clinics in the hospital system, and consequently, neither patient had been able to discuss her concerns about medical intervention in pregnancy before admission for labor and delivery.

An analysis of the ethical concerns of the physicians who sought court-ordered intervention in each of these cases reveals four distinct areas of reasoning.

(1) There is concern for the innate value of fetal life in the third trimester that motivates forced intervention on rare occasions based on the principle of beneficence. There has been a general consensus explained most distinctly in the language of *Roe v Wade*, that society shares a protective concern for the viable third-trimester fetus.[15] Arguments based on theologic tenets and moral philosophy amplify at least this degree of concern for the fetus.[19] Regardless of the source of one's opinion of postviability fetal value, physicians have traditionally been reluctant to perform in a fashion that ignores the value of fetal life at term. Such a respect for fetal life was described in a policy statement published by the American College of Obstetricians and Gynecologists in 1977. A portion of that statement sought to explain the concept of fetal value, which is especially pertinent to discussions of the third-trimester fetus.

> Since the status of the fetus involves widely divergent theological and philosophical opinions in a pluralistic society, unanimity should not be expected. However, there appears to be a greater agreement on this matter than some physician statements suggest. This agreement is to be found in a general consensus in at least two main areas: 1) without going at length into the basis of the difference, the fetus has a qualitatively different nature and value from that of other human tissues or organs and 2) this value derives, at least in part, from its potential for developing into an obvious member of the human family. The value of the fetus is thus related to that placed on all human beings. It is therefore not possible fully to dissociate fetal life from human life so as to disvalue the one without posing some measure of threat, however subtle, to the value of the other.[20]

(2) The unique relationship of mother and fetus, especially in the third trimester, makes the physician-patient obligation a motivating factor in obstetric decision-making. The obstetrician has long recognized the presence of two pateints to whom the physician is obligated in the third trimester. Advances in perinatology have emphasized electronic, ultrasonographic, and biochemical fetal surveillance techniques that identify the viable fetus as a patient for whom the obstetrician cares.[21] Contemporary ethical theories of contractualism recognize that uniquely dual obligations inherent to the obstetric contract between physician and

patient exist once a woman allows her pregnancy to progress to a point of fetal viability or near-term gestation.[22] Even authors who oppose court-ordered intervention admit the unique maternal-fetal contractual approach to obstetric decision-making.[23] No other dual patient relationship approximates the total interdependence of mother and fetus at term gestation. Therefore those who propose that therapy always be directed toward the patient's (or patients' in this situation) best interests are compelled to take both mother and fetus into consideration during the third trimester.

(3) The physician must assess the reasonableness and rationality of patient demands. Ready acquiescence to the demands of a patient possibly suffering from an affective disorder, such as in case No. 2, would be problematic for any physician who viewed her request as being irrational. Patient requests for termination of viable fetal life (not just an end to pregnancy), as that reported in case 1, may be viewed as being unreasonable by physicians and many others in society.[24] As noted by Veatch,[25] a demand for reasonableness is essential to adequate medical decision-making in our society. In the face of requests that appear so opposed to societal norms, physicians may feel compelled to seek to overrule a patient's demands with court-ordered intervention. Failure to intervene, as in case 1, results in an unacceptable loss of fetal life at term and a profound dissatisfaction among the health care team with the care provided. In case 2, after delivery the mother requested to keep her newborn baby and indicated after the fact an understanding of the intervention needed for her baby to survive.

(4) The potentially permanent damage to a fellow person born disabled as a result of aberrant in utero decision-making is a heavy burden for physicians, society as a whole, the family, and especially the newborn potentially subjected to a lifetime of suffering. Physicians who favor a "burdens v benefit" ratio approach to these types of medical decision-making dilemmas are extremely concerned about nonintervention when such a result is possible. In such a direct medical management approach, or a burdens versus benefits approach, cesarean section would be selected when the risk of nonintervention is seen as excessively high (resulting in either fetal death or newborn disability) and the risk of maternal morbidity/mortality sufficiently low to justify surgical intervention.[26] The Committee on Bioethics of the American Academy of Pediatrics has recently published a statement on maternal-fetal conflict that supports this very premise.[27] In keeping with this model, some physicians feel compelled to intervene because of the history and tradition of principles emphasized by long-standing codes of medical ethics, such as the Hippocratic Oath, that encourage beneficence and nonmaleficence in physician actions.[28] The very real chance that lifelong physical or mental impairment of a newborn could develop from nonintervention creates concerns about both individual and distributive justice, as well as economic utility.

We oppose seeking court-ordered intervention except in the most unusual and atypical of situations. Because of a deep respect for maternal autonomy, such times should be exceedingly rare. For example, court intervention has been sought in less than one case per 10,000 deliveries at the two institutions involved in these cases. However, even in an era when autonomy, individual rights and privacy have achieved a high priority in contemporary ethical theory, the maternal-fetal conflicts discussed demand a balancing emphasis on the obligations found in the concepts of community, commitment, family life, and childbearing that others have shown to limit the absoluteness of autonomy.[29, 30] Only total denial of fetal value and sole concern for maternal autonomy will ever justify complete prohibition of court-approved medical intervention to assist a third-trimester fetus against maternal wishes in all situations.

The cases in this article represent unusual instances in which physicians felt compelled to seek court-ordered intervention for the many reasons mentioned. Such compelling situations are rare. Physician awareness of these dilemmas can frequently prevent such situations. However, even if prenatal discussions of such issues become routine for all patients, there will continue to be an occasional situation that must be managed individually, with methods that may include court-ordered intervention, to provide medically reasonable and ethically acceptable obstetric care. As shown by these cases, the rare instance occurs in which reasonable certainty of in utero death or newborn disability is present for a term fetus without surgical intervention, reasonable expectation is present for the surgery to result in the birth of a live newborn with a good prognosis, and maternal refusal of surgery all coexist. When the significance of a third-trimester fetal death or a lifetime of permanent physical or mental disability is balanced against the demand to uphold maternal autonomy at all costs, the recognized ethical principles of beneficence, non-maleficence, justice, obstetric contract keeping, and acting in the patients' best interests combine in rare situations to challenge and override concerns for individual maternal autonomy.

Removing a retained placenta by oxytocin—A controlled study

Charlotte Wilken-Jensen, MD, Verner Strøm, MD, Meta Damkjær Nielsen, MSc, and Bo Rosenkilde-Gram, MD

Gentofte, Denmark

No increase in maternal plasma oxytocin concentration was detected after administration of 100 IU oxytocin into the umbilical veins of seven women immediately after delivery. The delivery of the placenta was accelerated after umbilical vein injection of 100 IU oxytocin in a placebo-controlled study of 40 women: 12 minutes (4 to 40) in the oxytocin group versus 40 minutes (29 to 40) in the placebo group (median and interquartile ranges), $p < 0.05$. (AM J OBSTET GYNECOL 1989;161:155-6.)

Key words: Oxytocin, retained placenta, umbilical vein administration

In 1983 Golan et al.[1] published a new method for removal of a retained placenta by injecting 100 IU of oxytocin into the vein of the umbilical cord. The work of Golan et al. was an open study and the originally published dose of 100 IU of oxytocin was later corrected to 10 IU. This dose was ineffective in a later published study.[2] We have studied oxytocin concentration in the maternal circulation after a bolus injection of 100 IU of oxytocin into the vein of the umbilical cord and performed a prospective, double-blind, randomized trial that was based on that dose.

Material and methods

Design and participants. To study the passage of oxytocin across the placenta, 10 ml of oxytocin (Syntocinon, 10 IU/ml, Sandoz, Basel, Switzerland) diluted in 20 ml of 0.9% sodium chloride was injected into the umbilical vein immediately after delivery in seven patients. Blood samples from the laboring women were collected before the injection and without intervals consecutively until delivery of the placenta.

Oxytocin and placebo ampules were supplied by Sandoz A/S, Denmark.

In the second part of the study 40 consecutive laboring women with a retained placenta were randomized to injection of either 10 ml oxytocin (10 IU/ml) mixed with 20 ml of 0.9% sodium chloride or 30 ml of sodium chloride into the vein of the umbilical cord. The placenta was regarded as retained if it was not expelled within 20 minutes after delivery of the infant, applying intermittent traction on the umbilical cord and light suprapubic pressure. All deliveries were vaginal, either spontaneously or by vacuum extraction. Methylergotamine, 0.2 mg, was given intramuscularly at delivery of the first shoulder.

The two groups were comparable with regard to age, gestational age, parity, former retained placenta, oxytocin augmentation in labor, duration of labor, number of vacuum extractions, sex, and weight of the infant ($p > 0.05$).

Blood pressure, pulse rate, and blood loss were noted, both before and after the injection. Heavy bleeding that demanded immediate removal of the placenta was the only criterion for exclusion. If the placenta was not delivered within 40 minutes after the injection, it was removed manually with the patient under general anesthesia.

Informed consent was obtained from all patients. The study was approved by the local ethics committee. In the first part of the study oxytocin in the maternal blood was measured by radioimmunoassay after acetone extraction and intensive purification.

Statistics. Wilcoxon matched-pairs rank-sum test was used to evaluate the open part of the study. The Mann-Whitney two-sample rank-sum test was used to evaluate the controlled portion of the study. Differences resulting in $p < 0.05$ were considered significant.

Results

Oxytocin concentration in maternal blood did not increase significantly at any time from the time of intraumbilical injection of the 100 IU of oxytocin to the

delivery of the placenta in any of the seven patients in the open portion of the study. The median concentration after injection was 11 (range, 7 to 19) μU/ml. The median time passed from injection to delivery of the placenta was 5 minutes (range, 1 to 7).

In the controlled portion of the study, 19 women received the placebo injection and 18 women received oxytocin. The time from injection until the placenta was delivered was significantly shorter in the oxytocin-treated group than in the control group: 12 minutes (range, 4 to 40) versus 40 minutes (range, 29 to 40) (median and interquartile range, $p < 0.05$). Five patients in the oxytocin group and 11 in the control group had the placenta removed manually. In the oxytocin group hemorrhage was 330 ml compared with 370 ml in the control group; this difference was not significant. No differences in blood pressure or pulse rate were observed.

Comment

Because of concerns of side effects after 100 IU of oxytocin was injected into the umbilical vein, we measured the maternal concentration of oxytocin in seven patients and found no significant increase. To our knowledge no other studies are available for comparison. Previous studies of the effect of intraumbilical oxytocin on a retained placenta have not been double-blinded, the dose of oxytocin has only been 10 IU, or the injection has been given only 5 minutes after delivery.

Our study appears to demonstrate that a 100 IU injection of oxytocin into the umbilical cord for the delivery of a retained placenta is safe and has a high success rate.

The use of transvaginal ultrasonography in the diagnosis of ectopic pregnancy

Ilan E. Timor-Tritsch, MD, Ming N. Yeh, MD, David B. Peisner, MD, Karen B. Lesser, MD, and Theresa A. Slavik, BA, RDMS

New York, New York

Despite advances in diagnosis made by the introduction of serum β-subunit of human chorionic gonadotropin determinations and transabdominal ultrasonography, ectopic gestations still present a major diagnostic challenge. The increased resolution of the transvaginally introduced high-frequency ultrasound transducer probes seems to solve this diagnostic problem. In this study 145 patients were referred for ultrasonographic workup because of a suspected ectopic gestation. In 38 patients a diagnosis could be made with classical transabdominal scanning. One hundred seventeen patients required additional transvaginal scanning with a 5.0 and a 6.5 MHz probe. In 98 patients a diagnosis was made during the first transvaginal scan; nine patients were rescanned within 3 days for the final diagnosis. In 56 patients, ectopic pregnancy was successfully ruled out by transvaginal scanning. Thirty-nine ectopic pregnancies were diagnosed. Only one false-positive identification was made. The sensitivity of diagnosing ectopic pregnancy by high-frequency transvaginal sonography was 100%; the specificity was 98.2%. The positive predictive value of this method was 98%, and the negative predictive value was 100%. The rate of the beating fetal heart was seen in the tube (23%). The high number of unruptured tubal pregnancies in this series (66%) suggests the possibility of an early diagnosis that may have therapeutic implications. The use of higher-frequency transvaginal transducer probes improves the diagnosis of the ectopic gestation. (Am J Obstet Gynecol 1989;161:157-61.)

Key words: Pregnancy, ectopic pregnancy, ultrasonographic studies, transvaginal ultrasonography, endovaginal ultrasonography

Ectopic pregnancy remains a major clinical diagnostic challenge. The combined use of transabdominal sonography and serum β-sub unit of human chorionic gonadotropin (β-hCG) determinations has resulted in a relatively high accuracy (70% to 95%) in predicting ectopic pregnancy.[1-6] The gestational age at which this "accuracy" of diagnosis is reached and the ratio of ruptured versus unruptured fallopian tubes is seldom reported. In 1980 Levi and Lebliq[7] reported a false-positive rate of 3% to 30% (mean 16%) and a false-negative rate of 2% to 35% (mean 5%) in making the correct diagnosis of ectopic gestation with transabdominal sonography. Romero et al.[4] used the "discriminatory β-hCG" level to predict the presence or the absence of ectopic pregnancy. By using the definition of the "discriminatory β-hCG" level, the absence of a normal intrauterine gestational sac with a titer of 6500 mIU/ml had a sensitivity of 100% and a specificity of 96%. The positive and negative predictive values in establishing the diagnosis of ectopic pregnancy were 86% and 100%, respectively. However, in most reports the specificity and the sensitivity for making the correct diagnosis of ectopic pregnancy by transabdominal sonography were 97% and 77% to 88%, respectively.[1-6]

The introduction of transvaginal transducer probes, particularly those with scanning frequencies as high as 7.0 MHz, presents a new opportunity to review pelvic organ morphologic features.[8,9] The high resolution of the picture enables the sonographer to focus on the fallopian tube. Attention has been directed to the early and reliable imaging of tubal gestations.[10,11]

The purpose of this study was to determine the effectiveness of transvaginal sonography in the management of ectopic pregnancy to make an early diagnosis. Both are a result of the technique of producing high-resolution pictures of the pelvic organs involved.

Material and methods

One hundred forty-five patients were referred for ultrasonographic examination over 1-year period (beginning in March 1987) because of suspected ectopic pregnancy. In 38 patients an unequivocal diagnosis was reached with transabdominal sonography. In 117 cases in which a definite ultrasonographic diagnosis could not be reached by transabdominal sonography, im-

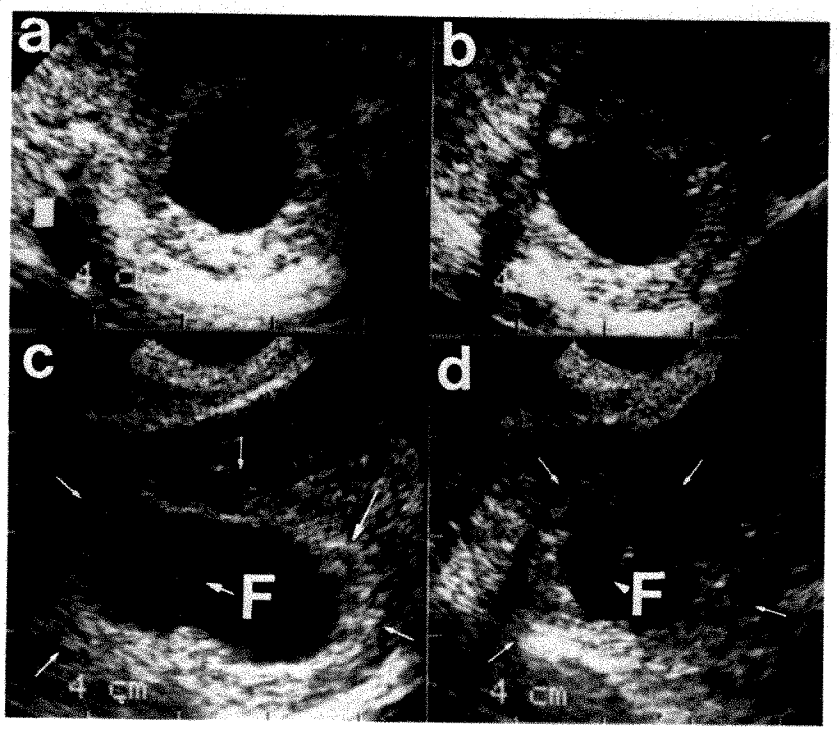

Fig. 1. Serial cross sections (**a, b,** and **d**) and a longitudinal section (**c**) of a thick-walled tube, containing fetal echoes *(F)*. The echogenic "tubal ring" is outstanding in the adnexa. This was a 7-week-old, unruptured tubal gestation with no fetal heartbeats at the time of the scanning.

mediate additional scanning was performed via the transvaginal route. A serum β-hCG test was performed in all patients. In most cases the test results were known by the sonographers. The transabdominal sonography and transvaginal sonography were performed by different persons.

The equipment used in the study included a General Electric 3000 scanner to which a 5.0 MHz 90-degree fixed-angle phased-array vaginal probe was attached; an Elscint ESI-1000 scanner with a variable angle, 6.5 MHz mechanical sector scanner transvaginal probe was used. After coupling gel was applied to the tip of the probe, it was inserted into one of the digits of a surgical rubber glove. The detailed scanning technique has been described in earlier reports.[10]

A tubal gestation was diagnosed if the uterus did not show signs of a normal or abnormal pregnancy and one or more of the following structures were observed: (1) a gestational sac or a yolk sac, or both, or fetal heartbeats within a thickened "tubal ring" (Fig. 1); (2) free pelvic fluid containing particulate matter (i.e., blood) with or without a coexisting thickened tube or parts of it (sometimes discrete blood clots could be seen and diagnosed). A positive result of the qualitative or quantitative serum β-hCG pregnancy test indicated that a pregnancy was present. In a minority of cases, the result of the pregnancy test was still pending at the time of the scan.

The outcomes of surgical procedures such as laparoscopy, laparotomy, curettage, culdocentesis, or clinical follow-up were recorded.

Results

In 38 of the 145 patients referred for ultrasonographic studies, the conclusive diagnosis of intrauterine pregnancy (normal or abnormal) or ectopic pregnancy could be made by transabdominal scanning. This group is referred to as the *transabdominal sonography group*. In 37 patients the diagnosis was made on the basis of the detection or absence of fetal heartbeat, indicating a normal or abnormal intrauterine gestation. In one additional patient, a tubal gestation was diagnosed when the fetal heartbeat was clearly visible outside the uterine cavity. Therefore, these 38 patients did not require additional transvaginal imaging. In the remaining 117 patients, the transabdominal sonography showed indirect ultrasonographic signs of an "empty uterus," "adnexal masses," or "free fluid" but was not conclusive enough to warrant an unequivocally positive or negative diagnosis of ectopic pregnancy. These patients had immediate transvaginal sonography. This group is referred to as the *transvaginal sonography group*. Two subgroups, categorized by the results, were created and are defined below.

Subgroup 1. In 98 of the 117 vaginally scanned patients a final diagnosis could be reached at the time of

Table I. Results of scanning 114 patients for suspected ectopic pregnancy

	Transabdominal sonography	*Transvaginal sonography*		*Total*

the first scan. No ectopic pregnancy was found in 49 of these 98 patients. A live intrauterine pregnancy was visible in 28 patients, and an abnormal gestation (no heartbeats) was found in 10. In the remaining 11 patients other pelvic pathologic conditions were found. In these patients the pending serum β-hCG level was obtained after the completion of the vaginal scan, excluding the presence of any pregnancy. The reasons for not excluding these patients from the study are discussed in the Comment section. All but one of the normal intrauterine gestations had a menstrual age of ≤7 weeks; one patient had a 9½-week intrauterine pregnancy but her extreme obesity prevented transabdominal sonography from making this diagnosis.

Ectopic pregnancy was diagnosed in 49 of the 98 patients. Four patients with distinct "tubal rings," a minimal amount of free pelvic fluid, and no visible fetal heartbeats were followed up until serially determined serum β-hCG dropped to nonpregnant levels and transvaginal sonography failed to image the previously present tubal pathologic condition. Forty-five of these 49 patients underwent laparotomy. In 43, tubal ectopic pregnancy was found. One patient had a ruptured ovarian pregnancy. In one patient no ectopic pregnancy was found. This last patient had a previous ectopic pregnancy and was first seen with an extremely tender adnexal mass. She had a positive urine pregnancy test in the emergency room. The transabdominal sonography showed an adnexal mass. A "tubal ring" was diagnosed by transvaginal sonography. Some blood was also seen. Because of the clinical signs of an acute lower abdominal disease, she was taken to the operating room before the serum β-hCG result was obtained. The next day the serum β-hCG titer was reported to be below pregnancy levels. Further review of the films revealed that the corpus luteum was misinterpreted for a "tubal ring."

Subgroup 2. Nine of the 117 vaginally scanned patients were rescanned within 3 days because the initial scan was not conclusive. No ultrasonographic or clinical signs of impending danger existed in these patients; therefore a subsequent scan was planned within 3 days. After rescanning the following results were found: tubal gestation without heartbeats (confirmed at surgery) in two patients, a very early normal intrauterine pregnancy in three patients, and an abnormal gestation in two patients. Two additional patients in this group had a corpus luteum cyst with no pregnancy. Although this group consisted of only nine patients, it seemed to pose the most problems for the ultrasonographers. The scanning time was almost double the approximate mean scanning time (23 minutes) of the previous groups. Because neither ectopic pregnancy nor intrauterine pregnancy could be visualized, the report relied heavily on the result of the quantitative serum β-hCG test, which often was unavailable at the time of the scan. Thirty-three of the 50 true ectopic pregnancies diagnosed by transvaginal sonography were unruptured (66%). In 17 patients a ruptured tube or a tubal abortion was found (34%). In 11 of the 50 ectopic pregnancies that were correctly diagnosed in this series, fetal heartbeats were detected (22%). In 18 cases, various amounts of blood were aspirated from the pelvis; in two patients the amount of blood exceeded 200 ml. The results of scanning are presented in Table I.

The statistical analysis regarding the diagnostic precision of the 117 vaginally scanned patients had the following results: No false-negative but one false-positive identification was made. Therefore the diagnostic sensitivity was 100%, whereas the specificity was 98.2%. The positive and negative predictive values were 98% and 100%, respectively. When all 145 patients in the group referred for ectopic pregnancy workup were analyzed, the specificity of the combined

transabdominal sonography and transvaginal sonography diagnostic procedures rose to 98.9%, and their positive predictive value increased to 98.1%.

Comment

Because of their physical properties, the 5.0 and the 6.5 MHz transducer probes produce images with higher resolution. The "unobstructed view" of the pelvic organs as a result of the vaginally introduced probe becomes obvious to the ultrasonographer early in the experience with this technique. The increased accuracy of transvaginal sonography in the diagnosis of ectopic pregnancy is the result of a combination of two components: first, its effective use in the diagnosis of the early intrauterine pregnancy, and second, its capability for imaging the abnormal (and sometimes the normal) fallopian tube. When transvaginal sonography is compared with transabdominal sonography, the normal intrauterine pregnancy, early embryonic structures, and the abnormal pregnancy may be detected about 1 week earlier with transvaginal sonography.[12, 13] A normal 4½-week intrauterine pregnancy is consistently detected by transvaginal sonography.[12]

One effective way to rule out ectopic pregnancy is by diagnosing an intrauterine pregnancy. Every ultrasonography laboratory should be aware of its own "discriminatory β-hCG zone" at which a certain transducer probe detects the earliest normal intrauterine pregnancy. This term, introduced by Kadar et al.[14] is now widely used but has to be determined in each ultrasonography laboratory for each of the different transducers.

Discriminatory β-hCG zones for vaginal probes are now being reported by authors.[15] As mentioned before, these zones should be determined for each vaginal probe and for each laboratory.

Despite the fact that the "discriminatory zone" for our probes was determined, we elected not to use them because occasionally only the qualitative β-hCG result was available. The only criterion regarding this laboratory test was whether it was indicative of a pregnancy.

The second component of the diagnostic algorithm is the direct examination of the fallopian tube.[9] The normal tube may be seen by transvaginal sonography if fluid surrounds it. If fluid is detected in the pouch of Douglas, every effort should be made to image the tube. When the tubal lumen is filled with fluid, a gestational sac, or a blood clot, imaging is easier. The "adnexal mass" detected with transabdominal sonography may be better evaluated with the higher resolution vaginal probe, and the diagnosis of "adnexal ring" can now be replaced with the more specific term "tubal ring."

The fact that fetal heartbeats were seen in 22% of the cases in this series, compared with the 5% to 10% detection by transabdominal sonography,[3] supports the assumption that transvaginal sonography provides the opportunity for detecting ectopic pregnancy at an earlier stage when tubal abortion or even tubal rupture has not yet occurred. The ratio of unruptured to ruptured tubal gestations and tubal abortions in this series (66% to 34%) at the time of the diagnosis adds additional support to the fact that the correct diagnosis is made at a relatively early stage when the gestational sac is still intact. The review of the literature supports the fact that with the improvement of the diagnosis over time, the percentage of intact tubal gestations at the time of diagnosis increases.[16]

Even the smallest amounts of free pelvic fluid may easily and consistently be detected by transvaginal sonography.[17] All ruptured ectopic gestations had some amount of free pelvic fluid at the time of the vaginal scan. Only two of the patients had >200 ml of blood in the abdominal cavity. However, in our cases in which the tubes were found to be intact, there were variable but small amounts of free fluid in the pelvis. Easy evaluation of the presence or absence of fluid in the cul-de-sac in cases of suspected ectopic pregnancy has important and practical clinical implications. The correct diagnosis in these cases may require clinical experience. However, even a relatively inexperienced operator during a busy night call in the emergency ward can make important decisions based on very simple but reliable findings, such as the presence or absence of life-threatening bleeding originating from a ruptured ectopic pregnancy. The exclusion of such a clinical situation may save the patient (and the physician) from unnecessary surgery. The final diagnosis may be left to a subsequent scan by a more experienced ultrasonographer.

We mention the various transvaginal images that may cause differential diagnostic problems for the ultrasonographer. Four structures should be carefully examined and correctly recognized:

1. The corpus luteum, which is eccentrically located within the ovary, surrounded by ovarian tissue, may create the impression of a "tubal ring."
2. A graafian follicle of the ovary has a wall that is usually thinner than the corpus luteum and the "tubal ring."
3. Small bowel—Difficulty in differentiating this from a tubal structure arises only if a static film is read. During real-time scanning, the peristalsis of the bowel is obvious.
4. Tubal pathologic conditions, such as a hydrosalpinx, which tends to be larger in size, is pear-shaped, and contains a homogeneous (mostly sonolucent) fluid.

Generally, the diagnosis of a tubal gestation should be made after a meticulous examination, with different and multiple scanning planes that prove the reproducibility of the structure. The diagnosis must be made during real-time scanning.

In our review of the false-positive case, an alternate

method for awaiting the final hormonal assay, such as laparoscopy preceding the planned laparotomy, would have avoided the surgical procedure.

The 13 cases referred to us to rule out ectopic pregnancy that subsequently had nonpregnant levels of β-hCG merit explanation. These cases were intentionally included in the study because they were part of the "rule out ectopic pregnancy" population with which every ultrasonography laboratory deals daily. It would be ideal to scan only those patients with an available β-hCG report. Unfortunately, the practice of emergency medicine does not always allow this. This was also true for this group of 13 patients. At the time of referral, results of their hormonal tests were pending. The patients were scanned before the results were known; a variety of pelvic pathologic conditions other than ectopic pregnancy were detected. Among the findings were corpus luteum cysts, simple cysts, and a hydrosalpinx.

In four cases, the diagnosis of a tubal pregnancy was not proved by surgical means. Therefore it is difficult to accept the validity of a diagnosis of ectopic pregnancy without pathologic confirmation. However, the reliability of the positive findings obtained by transvaginal sonography, such as the empty uterus, a "tubal ring" with an embryonic pole, absence of pelvic bleeding in the presence of falling levels of β-hCG in a patient who never passed blood, or tissue through the cervix, complies with the diagnosis of "missed ectopic pregnancy" even by the strictest standards. The clearly visualized "tubal ring" regressed in all three cases within 10 to 15 days, along with the falling hormone levels. More experience with conservatively managed cases may lead to acceptable clinical management of certain small-size tubal gestations with absent fetal heartbeats and a declining titer of β-hCG. Subsequent tubal patency in these cases should be further investigated.

We emphasize the importance of first documenting the presence of a pregnancy with qualitative β-hCG determinations before transvaginal sonography is performed. Furthermore, it is important to obtain serial quantitative serum β-hCG levels in patients with suspected ectopic pregnancies, (or early intrauterine gestations) who have a stable clinical condition.

We believe the transvaginal route, preferably with a higher-frequency probe, is the test of choice in the reliable and early ultrasonographic workup of the patient with suspected ectopic pregnancy.

Addendum

At the time of this publication the total number of patients scanned vaginally was 202. Eighty-three true ectopic gestations were found. One false-positive case and one false-negative case were also seen. The specificity and sensitivity of the test did not change significantly (99.1% and 98.8%, respectively). The positive and negative predictive values of the test were 98.8% and 99.1%, respectively.

Ileocecal vaginal construction

Rainer A. Bürger, MD,[a] Hubertus Riedmiller, MD,[1] Paul G. Knapstein, MD,[b] Volker Friedberg, MD,[b] and Rudolf Hohenfellner, MD[a]

Mainz, West Germany

In 10 patients, six with previously failed vaginal reconstruction of Mayer-Rokitansky syndrome, two with male pseudohermaphroditism, one with a history of Wertheim-Meigs operation followed by irradiation of the true pelvis, and one with vaginectomy caused by trauma, a neovagina was created out of cecal or ileocecal segments. Advantages of this technique are the excellent blood supply to the ileocecal region and the long vascular pedicle. The supplemental application of terminal ileum for prolongation of the cecal vaginoplasty allows for tensionless anastomosis between the neovagina and the vulva, even in patients with difficult anatomic conditions. A detailed description of the operative technique and indications for ileocecal and cecal vaginoplasty are presented, and the techniques in current use for vaginal replacement are reviewed and discussed. (Am J Obstet Gynecol 1989;161:162-7.)

Key words: Vaginal aplasia, reconstruction, ileocecal segments

Vaginal reconstruction may become necessary in cases of congenital vaginal aplasia and functional or traumatic vaginal loss. Of the variety of operative techniques currently available, only skin transplants[1-3] and sigmoid vaginoplasty[4, 5] have found widespread application. Until now, the use of cecum vaginal replacement has been described by Markland and Hastings[6]; in the current literature there is no mention of the use of ileocecal segments.

Two factors prompted the use of cecal and ileocecal segments for vaginal replacement: the extremely low morbidity rate observed in more than 120 patients in whom urinary bladder replacement was done with cecum, ascending colon, and terminal ileum[7] and the close topographic proximity of the cecum and terminal ileum to the vagina and thus the prospect of good acceptance of the material. The following report presents our technique of vaginal reconstruction, clinical experience in a small number of patients, and a comparison of this method with other techniques of vaginal reconstruction.

Material and methods

We have used cecum and ileocecal segments since April 1986 to create a neovagina in 10 patients, ages 16 to 34 years. Six of these patients had vaginal aplasia (Mayer-Rokitansky syndrome), with fibrotic shrinkage and total obliteration of the reconstructed vaginal tube, which occurred after creation of a peritoneal neovagina or after vaginal reconstruction with a free skin graft.

Hysterectomy and vaginectomy were performed in the seventh patient after a polytrauma with multiple pelvic injuries (rupture of the vagina, uterus, rectum, urethra, etc.). The eighth patient had a history of Wertheim-Meigs operation followed by irradiation of the true pelvis 5 years ago. The patient later developed a 2 cm deep vaginal groove. The remaining two patients had male pseudohermaphroditism.

Operative technique

The preoperative intestinal preparation of the patient was performed via colonic irrigation by means of a gastric tube with approximately 8 to 10 L of Ringer's lactated solution plus potassium chloride. Antibiotic prophylaxis was carried out perioperatively. To enable a combined abdominal and vaginal approach, the patient was placed in the supine position with lower extremities resting on adjustable leg supports. Access to the abdomen was provided via a lower medial abdominal incision approximately 3 inches above the navel. A description of the operative procedure, along with illustrations to visually demonstrate it, follows.

Fig. 1. Cecal pole and ascending colon are mobilized after a right-sided paracolic incision of the dorsal parietal peritoneum. Complete mobilization of the right colonic flexure is very important to ensure subsequent tension-free ileocolostomy. In obese patients, one must take special care to safeguard the right retroperitoneal ureter. Precise localization of the ileocolic artery via cold light diaphanoscopy must be accomplished before selection of the ileocecal segment to be isolated. A 12 to 15 cm segment of cecum and ascending colon with good

vessel supply is selected. The point of subsequent intestinal dissection is marked by four stay sutures.

Only the vessel arcade located between the ligatures next to the intestine will be dissected in this region. After appendectomy, the cecum should be moved caudally to ensure tension-free anastomosis to the vulva. If possible, the ileum is dissected close to Bauhin's valve.

Fig. 2. Bowel continuity is achieved by ileocolostomy with single-layered seromuscular sutures (PDS or Maxon 4/0) in which the narrow ileum and the wide colon ascendens are anastomosed in a fish-mouthed manner to compensate for the difference in diameter. After completion of the intestinal anastomosis, the mesenteric incision is closed by sutures. The dissected intestinal segment is cleansed with physiologic saline solution via an 18F balloon catheter in the ileum, and fecal remains are removed by suction through the lumen of the ascending colon.

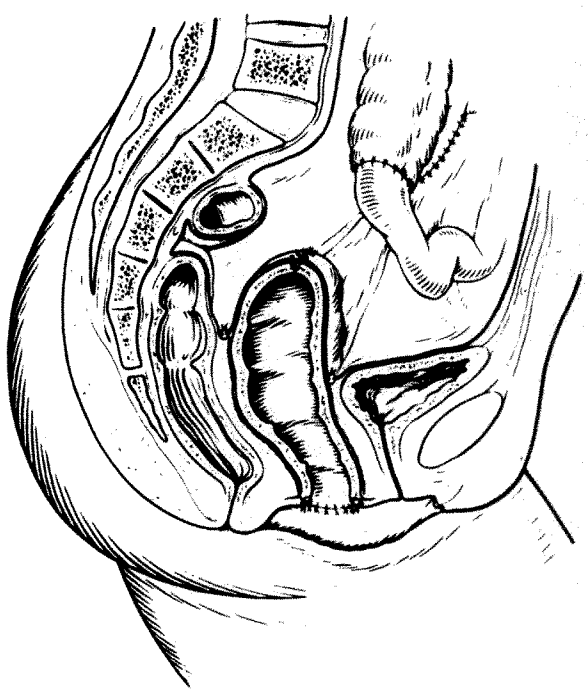

Fig. 11. See text for description.

Fig. 3. Simultaneously, a second operating team performs the vaginal approach. A pouch for the insertion of the intestine through the pelvic floor is created by an H-shaped incision in the vaginal groove between the urethral orifice and the posterior commissure. A canal is formed by spreading the tissue with the fingers and with scissors until the Douglas peritoneum has been reached.

Fig. 4. The taut tissue between the urethra and bladder on the one side and the rectum on the other side is cut in two with the scissors. After completion of this preparation, the canal is wide enough for three fingers up to the pelvic floor, which widens out cranially.

Depending on the length of the mesentery of the ileocecal segment that is to be used to form a neovagina, the following operative strategies should be observed.

Fig. 5. With normal insertion of the ileocolic artery, the cecum or ascending colon is rotated 180 degrees

Table I. Methods of treating vaginal aplasia or atresia[8,9]

1. Nonsurgical dilation according to Frank[10]
2. Surgical methods that use skin transplantation
   - Pedicle skin flaps or musculocutaneous flaps
   - Free skin cleavage grafts
   - Free skin cleavage grafts with use of a meshgraft technique
   - Free skin transplantation
3. Surgical methods that use epithelialization from outer skin
   - Simple formation of a vaginal tube with prothesis
   - Joining of labia majora
   - Lining of vaginal tube with peritoneum
   - Vecchietti method[11]
4. Surgical methods that use intestinal transplantations
   - Sigmoid vaginoplasty
   - Ileal vaginoplasty
   - Lining of vaginal tube with free mucosa–muscularis transplant made from small intestine

counterclockwise so that the margin of the ascending colon can be positioned without tension through the newly formed canal in the pelvic floor down to the vulva.

Fig. 6. High insertion of the ileocolic artery does not allow rotation. In this case the cecal pole is moved caudally through the canal in the pelvic floor down to the vulva. The ascending colon margin is closed, and the cecal pole at the vulva is opened by a horizontal incision.

Fig. 7. If the mesentery is 2 to 3 cm too short for positioning the cecal pole at the vulva, a horizontal incision of the parietal peritoneum above the supplying vessel arcade can usually lengthen the mesentery enough to attain a tensionless anastomosis with the vulval region.

Fig. 8. If the mesentery of the cecum is still too short, a 15 cm long ileal segment attached to the cecum is used for formation of the neovagina. In contrast to the mesentery of the ascending colon, the ileal mesentery must be dissected as far as possible toward the mesenteric end between ligatures to achieve a tensionless ileocolostomy. Dissection of the intestine is performed between the suture markers along the ileal margin and the margin in the colon ascendens region. Although it protects the vessel arcade near the bowel, the ileal segment is mobilized and positioned at the opening of the cecum. The U-shaped ileal segment is then positioned at the horizontally incised lower cecal pole and its mesentery incised lengthwise. By suturing the two intestinal edges with a running suture, a small pouch is formed and then anastomosed to the cecal pole with interrupted sutures to create a 5 to 7 cm extension of the neovagina.

Fig. 9. The completed neovagina is pulled through the canal in the pelvic floor.

Fig. 10. While the second operating team performs an anastomosis of the neovagina to the remaining vulva using interrupted sutures, the first operating team closes the abdomen after the neovagina has been attached to the lateral abdominal wall and a vaginal drain has been inserted.

Fig. 11. The sagittal cut through the pelvis shows the position of the neovagina as related to the other pelvic organs. By attaching the Douglas peritoneum to the wall of the neovagina, further extraperitonealization of the neovagina is accomplished.

The nasogastric tube should be left in place for 3 to 5 days after surgery; nutriments are administered intravenously until the first spontaneous stool passage, and coitus is expressly forbidden for 4 to 6 weeks.

Comment

Most methods for the treatment of aplasia or atresia of the vagina can be categorized as nonsurgical, such as dilatation, or surgical, such as skin transplants, intestinal transplants, or epithelialization from the outer skin layer (Table I).[8-11] Currently, the most popular surgical method is the formation of an artificial vaginal lumen lined with free transplanted split-thickness graft as described by Kirscher and Wagner[12] and improved on by McIndoe and Barnister.[3] Positive results brought about the wide use of this relatively simple and safe technique for more than 50 years. However, later examinations by Cali and Pratt[13] and Counseller[1] demonstrated a high shrinkage tendency in the upper third of the neovagina, with partial or complete obliteration in 21% to 41% of patients. This problem could not be corrected satisfactorily by meshgraft techniques, free bowel mucosa transplants, or lining the vaginal tube with peritoneum.[8, 14-16] In addition to the necessary dilatation of the vaginal canal or the lengthy wearing of a mold, these patients very often developed extended scarring at the skin transplant site, which in some cases led to keloid formation.[1, 3, 8, 15, 17] Various authors have described urethrovaginal fistulas and necroses of the urethra caused by the implanted mold.[1, 3] Bruck[14] believed that the main problem in the construction of an artificial vagina was not so much the formation of a hollow area but rather finding an appropriate lining that guarantees lasting patency of the neovagina.

At the turn of the century, the idea of using nonshrinking bowel as a vaginal replacement was proposed. Küstner, Snegireff, Baldwin, Albrecht, and Hochenegg were the first to prepare the way for ileal, rectal, and sigmoid transplants between 1892 and 1912.[17] The patients very often suffered from stool incontinence when the rectum was transplanted and experienced a high rate of mucous secretion (as much as 250 ml/day) when ileum was used.[9, 17] The sigmoid is topographically situated in a convenient position, possesses enough flexibility, and has an optimal blood supply with a sufficiently long and well-vascularized blood arcade. Further advantages of the sigmoid are a wide lumen and

only a slight tendency to traumatization involving postcoital bleeding. Occasionally lethal complications encountered in the first series of sigmoid vaginoplasties, such as thrombosis, strangulation ileus, and implant necrosis with ascending pelvioperitonitis caused by vessel distention, could be overcome by the modifications of Schmidt[4] and Zängl.[5]

The advantages of the sigmoid segment also apply to the cecum, which is particularly useful as vaginal replacement material in patients with insufficient size of the sigmoid segment, sigmoiddiverticulitis, extended sigmoid adhesions, or previous sigmoid resections. Until now, only Markland and Hastings[6] have published their experiences with the cecum as a vaginal substitute in five transsexual patients. Good results were achieved in these patients after clockwise rotation of the cecum on its axis and anastomosis of the distal end with a newly created vaginal orifice. We were also able to use this operative technique successfully in two patients. Because the ileocolic artery insertion was higher in the other two patients, we constructed a neovagina using cecum without rotation of the bowel segment to create a free anastomosis to the vulva. Despite complete mobilization of the right colonic flexure, it may not always be possible to achieve tension-free positioning of the cecum to the vaginal orifice. This problem has been described repeatedly in sigmoid transplants and by Markland and Hastings[6] in a cecal transplant. Sigmoid transplant rejection or necrosis must be related to tension between the anastomosed sigmoid and vaginal orifice.[4, 5] When the mesentery cannot be extended sufficiently as a result of horizontal incision of the peritoneum across the supplying vessel arcade (Fig. 7), the extension of the cecal vagina can be achieved by inclusion of the terminal ileum.

The 10 patients operated here had a complication-free postoperative course, minimal mucous secretion in the neovagina, and satisfactory function with no shrinkage tendency. In the polytraumatized patient, it was necessary to undertake vaginal reconstruction 2 months after surgery to correct a stenosis of the vaginal orifice with massive scar tissue formation.

In addition to vaginal aplasia or atresia, the operative technique described can be applied in cases of radical carcinoma surgery (total vaginectomy or anterior exenteration with simultaneous vaginal reconstruction[18, 19]), rectovaginal fistulas, radiogenic vaginal shrinkage (case No. 5), and in rare cases of vaginal agenesia with a functional uterus.[20]

The decision to attempt nonsurgical dilatation, surgery with skin transplants or epithelialization from the outer skin, or intestinal transplants must be based on the patient's anatomy, the number of previously failed operations, the surgeon's operative experience, and the psychologic well-being of the patient. On the basis of initial results in a small group of patients, it is possible to say that the previously described operative technique allows the treatment of various types of vaginal aplasia or atresia. Follow-up of 6 to 30 months has shown good cosmetic and functional results. No complications were observed within this time period.

The major advantages of a neovagina created from cecum or ileocecum can be summarized as follows: (1) excellent blood supply of the ileocecal region; (2) a longer vessel arcade of the anastomosed segment, which, when used in combination with the colon ascendens, can be extended as long as needed; (3) the possibility of rotating this segment 180 degrees without endangering the blood supply; (4) inclusion of the terminal ileum to form the neovagina when a higher insertion of the ileocolic artery is present; and (5) rapid decrease and almost total loss of mucous secretion.

Renal artery flow-velocity waveforms in normal and hypoxemic fetuses

S. Vyas, MD, K. H. Nicolaides, MD, and S. Campbell, MD
London, England

Color flow mapping was used to identify the fetal renal artery and to obtain flow-velocity waveforms. A reference range of the fetal renal artery pulsatility index with gestation was constructed from a cross-sectional study of 114 appropriate for gestational age fetuses of 17 to 43 weeks' gestation. The pulsatility index decreased linearly with gestation, indicating a fall in impedance to flow, and presumably an increase in renal perfusion. The renal artery pulsatility index was also determined in 18 small-for-gestational-age fetuses and was higher than the appropriate-for-gestational-age group. The small-for-gestational-age fetuses also had fetal blood sampling performed by cordocentesis. A significant, direct correlation was found between blood oxygen deficit and increased renal artery pulsatility index. (AM J OBSTET GYNECOL 1989;161:168-72.)

Key words: Fetal renal artery, color flow mapping, Doppler, cordocentesis, fetal hypoxemia

Fetal Doppler velocimetry in association with fetal blood sampling by cordocentesis allows examination of the effects of hypoxemia on the cardiovascular system of the human fetus.[1, 2] Fetal blood sampling by cordocentesis has provided evidence that some small-for-gestational-age (SGA) fetuses are hypoxemic, and Doppler studies have demonstrated that in fetal hypoxemia there is a redistribution of cardiac output that results in a brain-sparing effect.[3-6] Thus in fetal hypoxemia there is an increase in the mean blood velocity and decrease in pulsatility index (PI) in the flow-velocity waveform from the common carotid artery, with a concomitant reduction in the mean blood velocity and increase in pulsatility index of flow velocity waveforms from the fetal descending thoracic aorta.[1, 5, 6] However, the characteristics of flow-velocity waveforms in the fetal aorta represent the summation of flow to the kidneys, other abdominal organs, the femoral arteries, and the placenta. Indeed the umbilical arteries, which are not under the control of the fetal homeostatic mechanisms, receive 50% of aortic blood flow.[7] Therefore study of the flow-velocity waveforms from branches of the abdominal aorta such as the renal arteries is likely to provide a more sensitive method for the prediction of fetal oxygenation than examination of aortic flow-velocity waveforms.

Study of the renal arteries has been limited by the inability of conventional B-mode ultrasonography to resolve small fetal vessels. This problem has been overcome by the introduction of color flow mapping. This article describes the method of obtaining flow-velocity waveforms from the renal artery and establishes references ranges for the pulsatility index of flow-velocity waveforms derived from this vessel.[8] Furthermore, it examines the relationship between renal artery pulsatility index Po_2 in blood samples obtained by cordocentesis from 18 SGA fetuses.

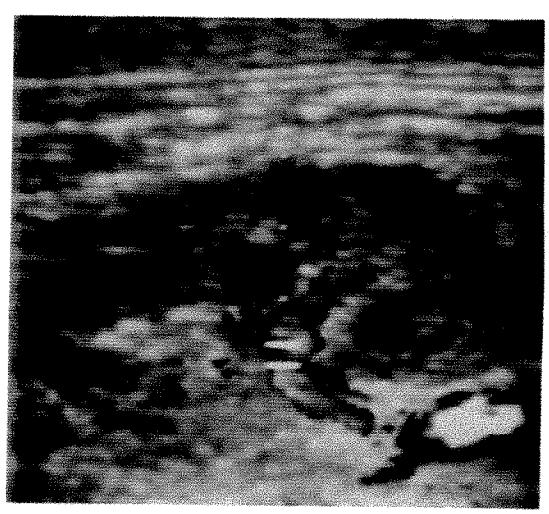

Fig. 1. Longitudinal axis of fetal kidney with renal artery *(red)* demonstrated by color flow mapping.

Patients and methods

A reference range for the fetal renal artery pulsatility index was derived from a single examination of 114 women with uncomplicated singleton pregnancies between 17 and 43 weeks' gestation. Gestational age was

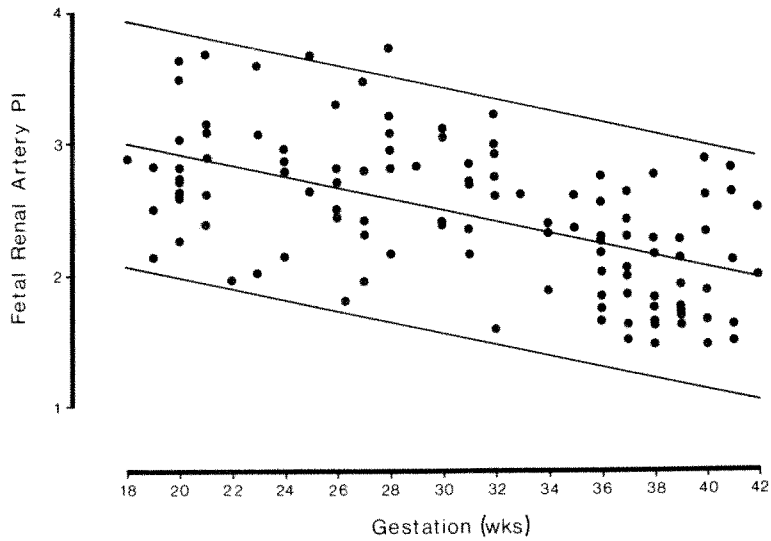

Fig. 2. Reference range (mean and individual 95% confidence intervals) of fetal renal artery pulsatility index with gestation constructed from study of 114 AGA fetuses (●).

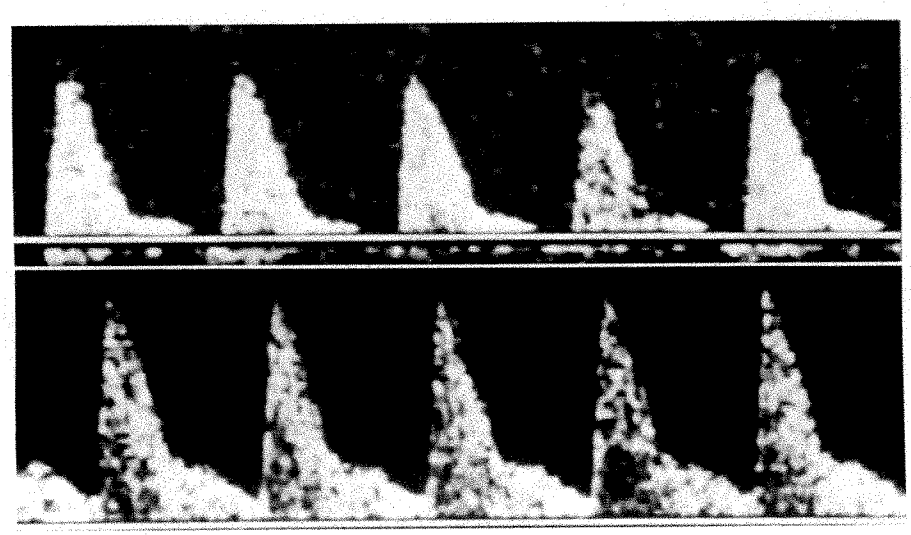

Fig. 3. Flow-velocity waveforms from the fetal renal artery at 26 *(top)* and 38 *(bottom)* weeks' gestation with absence of end-diastolic frequencies in the former and presence in the latter.

calculated by Naegele's rule and was confirmed by an ultrasonographic scan performed at 18 to 22 weeks of amenorrhea. The women were recruited from the antenatal clinic during their routine visit and had no pregnancy complications. Ultrasonographic examination at the time of the Doppler studies showed all the fetuses to be structurally normal and of appropriate size for gestational age (AGA). Furthermore, neither oligohydramnios nor polyhydramnios was present.

Studies of the fetal renal artery were performed with a color flow mapping system with a 5 MHz transducer (Acuson 128, Acuson) and a high-pass filter setting of 125 Hz. The patient was placed in a semirecumbent position and a longitudinal view of the fetal kidneys was obtained by real-time ultrasonography. All examinations were performed during fetal apnea because fetal breathing movements are known to have marked effects on fetal blood flow.[9] Fetal breathing movements are recognized by the rhythmic movement of the fetal kidneys independently of fetal trunk movements. The image of the kidney was magnified and the color flow mapping element of the transducer was started. Thus Doppler-shifted frequencies in the scan plane were colored either red (movement toward the transducer) or blue (movement away from the transducer). In the longitudinal plane the renal artery runs directly toward the transducer from its origin as a lateral branch of the abdominal aorta to the hilum of the kidney (Fig. 1).

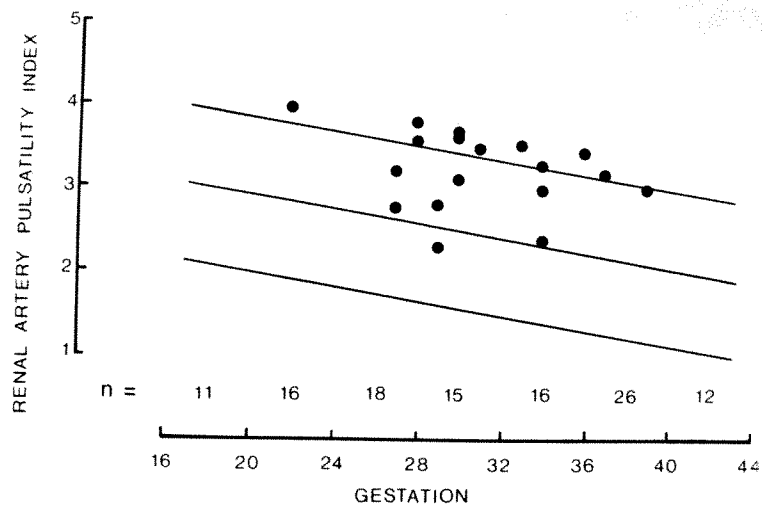

Fig. 4. Renal artery pulsatility index of 18 SGA fetuses (●) plotted on reference range.

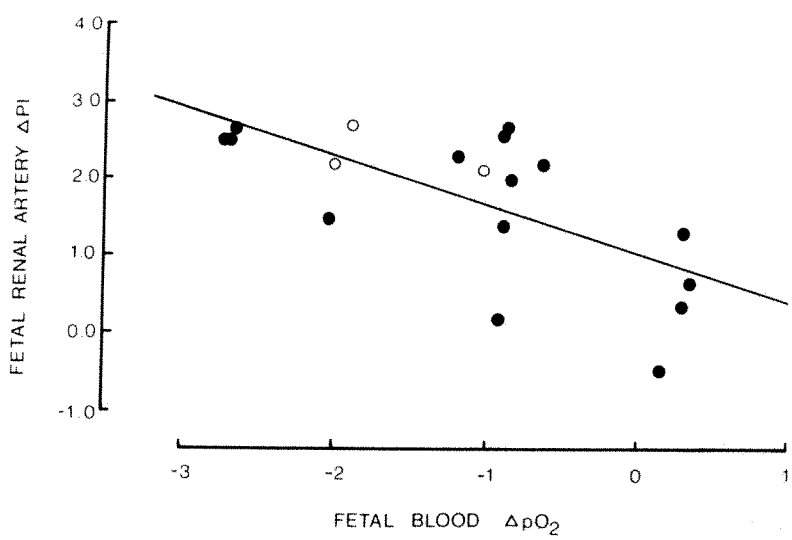

Fig. 5. Relationship between fetal hypoxemia and renal artery pulsatility index, both expressed as number of SDs by which observed blood Po_2 and renal artery pulsatility index differed from respective mean for gestational age. Pregnancies in which oligohydramnios was noted are indicated by ○.

The abdominal aorta lies parallel to the transducer. In this orientation the beam-vessel angle for the renal artery is close to 0 degrees, whereas the angle for the abdominal aorta is approximately 90 degrees. This ensures that the signals from the renal artery are optimized, with no contamination from the aorta. The Doppler range gate was placed over the renal artery instead of one of its branches. Flow-velocity waveforms were recorded and the pulsatility index was determined by an on-line spectrum analyzer (Doptek Ltd.).

The intraobserver coefficient of variation for the pulsatility index of flow-velocity waveforms for the renal artery was determined by examining three fetuses; 10 measurements were taken from each fetus during a 1-hour period. The intraobserver variation was 5.4%. Measurements were made from both the left and right fetal renal artery in 12 cases; no significant difference was found (Student's paired t test, $t_{11} = 0.21, p = 0.85$).

The fetal renal artery pulsatility index was also determined in 18 SGA fetuses who were referred to our unit for blood gas analysis and rapid karyotyping at gestational ages between 22 and 39 weeks. The fetal abdominal circumference was 2 to 7.5 SDs below the mean for gestation of our reference range, which was constructed from the study of 1610 pregnancies. The Doppler studies were performed up to 30 minutes before cordocentesis, which was performed without maternal sedation or fetal paralysis.[2] Blood vessels were identified by the intravascular injection of 0.4 ml normal saline solution at the time of cordocentesis.[2] The

umbilical vein was sampled in 14 cases and the umbilical artery was sampled in four cases. Fetal blood gases were measured by a Radiometer ABL 330 (Radiometer).

Linear regression analysis was used to calculate the mean and individual 95% confidence intervals of the relationship between renal artery pulsatility index and gestation. In the SGA fetuses the individual observed renal artery pulsatility index and blood Po_2 values were expressed as the number of SDs from the respective normal means for gestation (ΔPo_2, Δpulsatility index).[10] One-sample Student's t test was used to compare blood Po_2 and renal artery pulsatility index between the SGA and AGA groups.

Results

Fetal renal artery flow-velocity waveforms were successfully obtained from 114 of the 131 examinations attempted (87%). Failure to obtain flow-velocity waveforms was always the result of the relatively short depth of field imposed by a 5 MHz transducer and occurred in association with an extensive anterior placenta (eight cases) or when the fetal spine was posterior (nine cases).

The renal artery pulsatility index decreases linearly with gestation ($r = -0.56$, $p < 0.0001$, constant = 3.77, slope = −0.04, SD = 0.46; (Fig. 2). The flow-velocity waveforms are highly pulsatile; the presence of end-diastolic frequencies becomes more common with advancing gestation (Fig. 3). Thus end-diastolic frequencies were present in 3 of 27 cases (11%) at 18 to 25 weeks' gestation, 6 of 37 cases (19%) at 26 to 34 weeks, and 43 of 50 cases (86%) at 35 to 43 weeks' gestation.

The renal artery pulsatility index is significantly higher (Fig. 4) and the blood Po_2 is significantly lower in the SGA than in the AGA fetuses ($t_{17} = 6.86$, $p < 0.0001$ and $t_{17} = -3.40$, $p < 0.01$, respectively). Furthermore, in the SGA fetuses there is a significant correlation between Δpulsatility index and ΔPo_2 (Fig. 5, $r = -0.66$, $p < 0.005$, slope = −0.63, constant = 1.04, SD = 0.75). Oligohydramnios was noted in three of the SGA fetuses.[11]

Comment

Fetal renal artery flow-velocity waveforms can be obtained by the use of color flow mapping. Since end-diastolic frequencies are absent in 54% of cases, the pulsatility index was selected for analysis of the flow-velocity waveforms because this index is not dependent on end-diastolic frequencies for its calculation. Impedance to flow in the renal circulation decreases with advancing gestation.

If it is assumed that the arterial pressure remains constant, then fetal renal perfusion increases. This may offer an explanation for the increase in fetal urine production rate that occurs with advancing gestation.[12] This is in agreement with studies on chronically catheterized fetal lambs in which total renal blood flow (in milliliters per minute) and filtration fraction are significantly higher near term when compared with values earlier in the third trimester.[13]

Although the hourly fetal urine production rate does not continue to increase at gestations beyond 40 weeks, the renal artery pulsatility index continues to fall.[12] This finding suggests that the change in urine production rate at this gestation may not be a result of changes in renal perfusion. Robillard et al.[13] have shown in the chronically catheterized sheep model that near-term fetal lambs may be more sensitive to circulating vasopressin than younger fetuses.[13] It is possible that the cause of reduction in urine production rate near term in the human fetus represents a maturation of the renal rsponse to circulating vasopressin and therefore increased tubular reabsorption.

In SGA fetuses there is a direct relationship between hypoxia and the renal artery pulsatility index (Fig. 5). This relationship would be part of the redistribution of cardiac output that has been reported in hypoxic human fetuses to produce the brain-sparing effect. When the content of inspired oxygen is reduced in the pregnant ewe, circulation in the fetus is redistributed so that perfusion of the brain, heart, and adrenals is increased, whereas perfusion of the carcass, pulmonary, splenic, gut, and renal vascular beds is decreased.[14] Previous studies with Doppler ultrasonography have alluded to these changes in the human fetus. However, exact information about the perfusion of individual fetal organs has not been obtained because of the inability to visualize the arterial supply.[15]

Although reduced renal perfusion may result in a reduction in fetal urine production and therefore amniotic fluid volume, examination of the latter reflects the chronic state whereas the former represents the acute state. Thus oligohydramnios was noted in three of the SGA pregnancies, presumably as a result of chronic fetal hypoxemia (Fig. 5).

The use of color flow mapping to identify the fetal renal artery and to correlate changes in flow impedance with measurements of fetal blood Po_2 has enabled the demonstration of a direct relationship between fetal oxygenation and impedance to flow in the fetal renal circulation.

Twin pregnancy in premature ovarian failure after estrogen treatment: A case report

Lawrence Tang, MD, and Robert S. Sawers, MD
Birmingham, England

Spontaneous or pharmacologically induced reactivation of follicular development in patients with premature ovarian failure may occasionally result in successful singleton pregnancy. We report the first case of a dizygotic twin pregnancy after cyclic estrogen-progestin treatment in this condition. (Am J Obstet Gynecol 1989;161:172-3.)

Key words: Twin pregnancy, premature ovarian failure, estrogen treatment

Premature ovarian failure is diagnosed when hypergonadotropic amenorrhea occurs before the age of 40. Although it carries a poor fertility prognosis, spontaneous ovulation and pregnancy have been observed in few cases. Occasionally, rebound ovulation after withdrawal of cyclic estrogen-progestin treatment may produce a singleton pregnancy. To our knowledge, dizygotic twin pregnancy from such treatment has not been recorded.

Received for publication January 4, 1988; revised January 1, 1989; accepted February 15, 1989.
Reprint requests: Lawrence Tang, MD, MRCOG, Academic Department of Obstetrics and Gynecology, Birmingham Maternity Hospital, Queen Elizabeth Medical Centre, Edgbaston, Birmingham, England B15 2TG.

Case report

The patient, 32 years old, was first seen because of secondary amenorrhea and primary infertility. Her menarche was at the age of 12 with regular 28-day cycles until the age of 18 when she started to take oral contraceptives and continued use for the next 6 years. When she married no spontaneous menstrual period occurred after discontinuation of oral contraceptives for 1 year. Her past medical history and family history were unremarkable.

The patient weighed 47.5 kg and was 156 cm in height. She had normal secondary sexual development. Pelvic examination was normal except for an atrophic vagina and a small uterus.

She had no withdrawal bleeding after Provera challenge. Levels of both follicle-stimulating hormone (FSH) and luteinizing hormone (LH) were high when measured on three separate occasions (FSH >50 IU/L, normal 1 to 9 IU/L [Medical Research Council

78/549]; LH >120 IU/L, normal 1 to 12 IU/L [Medical Research Council 68/40]). Serum prolactin and thyroid function test results were normal. Complete blood count, urinalysis, liver function test, serum electrolytes, serum cholesterol, serum calcium and phosphate, and serum protein determinations were within normal limits. Chromosomal study showed a normal karyotype of 46,XX. Laparoscopy revealed a hypoplastic uterus, patent tubes, and small ovaries. Bilateral ovarian punch biopsies failed to demonstrate any primordial follicles. Seminal fluid analyses of her 33-year-old husband were normal.

After discussion with the couple about the poor fertility prognosis, the patient agreed to a 3-week trial course of ethinyl estradiol treatment at 50 μg daily. Weekly endocrine assessment showed gradual suppression of gonadotropin levels. The patient had withdrawal bleeding but no rebound ovulation after treatment for 6 months. She was then given buserelin (Hoechst U.K. Ltd.), a gonadotropin-releasing hormone analog, at a dose of 6 × 100 μg daily for 21 days followed by a 28-day drug-free period to observe for rebound ovulation. The gonadotropins were suppressed to normal levels but the serum estradiol level remained low; no rebound ovulation occurred after three treatment cycles. Subsequently adequate suppression of gonadotropins was achieved with ethinyl estradiol, which was followed by ovarian stimulation with clomiphene citrate (100 mg daily for 5 days) for three cycles and then human menopausal gonadotropin (2925 IU) for one cycle. All treatments failed to induce any follicular development.

The couple was counseled after 22 months of intensive treatment. The patient was started on a regimen of ethinyl estradiol, 100 μg daily for 28 days, with medroxyprogesterone acetate, 5 mg daily, for the last 10 days followed by a 28-day treatment-free period to await rebound ovulation. She had regular withdrawal bleeding for 6 months. In the seventh month, she had no withdrawal bleeding. Ultrasonographic scan showed a twin pregnancy. At 28 weeks' gestation, cesarean section was performed for severe proteinuric preeclampsia and no growth in the second twin. A male infant weighing 1160 gm and a female infant weighing 820 gm were delivered.

Comment

Accurate diagnosis of the cause of premature ovarian failure is the best guide to the likelihood of spontaneous ovulation and the aptness of the ovaries to respond to estrogen treatment or ovulation induction. Patients with ovarian failure after chemotherapy may respond readily, whereas autoimmune ovarian failure and resistant ovary syndrome are quite refractory to treatment. In idiopathic premature ovarian failure, a history of secondary amenorrhea or oligomenorrhea seems to have a better outcome than primary amenorrhea.[1] Patients with serum estradiol concentrations above menopausal range and/or serum LH levels greater than FSH levels are more likely to respond because the syndrome reflects the presence of intermittent ovarian follicular activity and appropriate feedback mechanism.[2] As illustrated in our patient, laparoscopic ovarian biopsy is not useful in the prediction of disease outcome because of inadequate sampling. Ovarian biopsy via laparotomy may help to diagnose autoimmune oophoritis or resistant ovary syndrome; however, postoperative adhesion formation may compromise fertility.

We believe that in vitro fertilization with oocyte donation should be recommended to those patients who are considered to be poor responders to ovulation induction. Both estrogen treatment and gonadotropin-releasing hormone analog can efficiently suppress the elevated gonadotropin levels. However, estrogen therapy is more successful in terms of ovulation induction because it can promote new FSH receptor formation by decreasing the down-regulation effects of high tonic levels of FSH and also synergizes with FSH to increase the number of FSH receptors.[1] For those who do not desire pregnancy or further pregnancies, estrogen replacement therapy should be started to prevent osteoporosis. However, in view of the unpredictable outcome and the remote possibility of a pregnancy, proper contraception or sterilization should be advised.[1]

Uterine development and endocrine relationships after menarche

Eleonora Porcu, MD, Stefano Venturoli, MD, Raffaella Fabbri, BSc, Luigi F. Orsini, MD, Emilia Sganga, MD, Lorena Brondelli, MD, Roberto Paradisi, MD, and Carlo Flamigni, MD

Bologna, Italy

Uterine volume and ovarian/uterine ratio during the first 6 postmenarchal years in 143 women were compared with an adult control group. Plasma gonadotropins and sex steroids were also correlated with uterine volume in adolescents. Uterine volume increased progressively and correlated positively with advancing postmenarchal ($r = 0.24$; $p < 0.05$) and chronologic ($r = 0.23$; $p < 0.05$) age. However, normal adult uterine volume was not yet reached by the highest postmenarchal (6 years) and chronologic (18 years) age. The ovarian/uterine ratio decreased gradually with increasing postmenarchal age but was always higher (0.22) than that of control subjects (0.12). Uterine volume correlated positively with plasma estradiol ($r = 0.25$; $p < 0.05$) and dehydroepiandrosterone ($r = 0.22$; $p < 0.05$) and its sulfate ($r = 0.22$; $p < 0.05$) levels. This study indicates that the uterus continues to grow after menarche in conjunction with increasing hormone levels. (Am J Obstet Gynecol 1989;161:174-7.)

Key words: Uterine development, adolescence, ovaries

In pubertal development, menarche is an intermediate step that is followed by further physical and endocrine changes. Some variables, such as height, skeletal maturation, and secondary sexual features, usually undergo minor modifications after menarche. On the other hand, the endocrine pattern shows more or less prolonged maturation toward normal ovulatory function.

As for the genital tract, maturation is not yet completed after menarche. From the onset of puberty to menarche, the ovaries gradually enlarge with an increase in the stroma and the number and size of antral follicles as documented by histologic and ultrasonographic studies.[1-4] Postmenarchal morphologic studies of the ovaries have been described by our group in previous studies.[5, 6] These studies have shown that at menarche ovarian volume is already in the adult range, often exceeding it, and that ovarian structure is frequently multifollicular. Before menarche, the uterus increases in size, and the cervix/corpus ratio decreases progressively.[4, 7]

This study defines the postmenarchal evolution of the uterus and its relationship with the reproductive endocrine background.

Material and methods

One hundred forty-three healthy teen-age girls (range, 13 to 18 years; mean, 16.2 years) were studied. The subjects ranged between 0.5 and 6 years (mean, 3.2 years) postmenarche. Each subject attended the hospital on an outpatient basis because of various nonendocrine disturbances. Mean (±standard deviation) height was 163 ± 4.6 cm, weight as 52.4 ± 7.6 kg, and body mass index was 20.9 ± 3.6 (normal range, 18 to 24). Each girl was at pubertal stages 4 and 5 in pubic hair and breast development according to Marshall and Tanner.[8] Menstrual rhythm varied between 18 and 90 days.

Thirty-three normal volunteers, normally menstruating, nulliparous, sexually mature, and 21 to 28 years of age, made up the control group. Height, weight, and body mass index were 165 ± 5.6 cm, 54.4 ± 2.3 kg, and 20.1 ± 1.7 (mean + SD), respectively. They had not used oral contraception for at least 12 months before the start of the study.

Blood samples were collected on the fifth day of the cycle and on a day between the tenth and the fourth before the next menstrual bleeding to evaluate the follicular and premenstrual endocrine pattern and the presence of ovulation. To evaluate frequency of ovulation, the girls were asked to record basal body temperature for at least 6 months.

The radioimmunoassay techniques used for hormonal measurements were previously reported.[6] In particular, follicular-stimulating hormone, luteinizing hormone, prolactin, 17-hydroxyprogesterone, proges-

terone, dehydroepiandrosterone and its sulfate, testosterone, androstenedione, 5α-dihydrotestosterone, estrone, and estradiol were assayed.

Ultrasound examinations of the uterus and ovaries were carried out by means of the full-bladder technique, with serial longitudinal and transverse scans of the pelvis in the supine position using one of three real-time ultrasound scanners. A 2.5 MHz mechanical sector scanner (Combison 100, Kretztechnik GmbH, Zipf, Austria) was used during the first period of our study. Two General Electric sector scanners (SRT with a 3 MHz transducer and RT 3000 with a 5 MHz transducer, General Electric, Milwaukee, Wis.) were subsequently used. Sonograms were performed during the early follicular phase.

Mean ovarian volume was considered representative of both ovaries in each subject. Uterine and ovarian volumes were determined by the formula for a prolate ellipsoid (volume = 0.5233 × D1 × D2 × D3, where D1, D2, and D3 are the three maximal longitudinal, anteroposterior, and traverse diameters).

Results are expressed as mean ± standard deviation, and the differences between the group means for large groups were tested with the use of the Students *t* test for unpaired data. Correlations between uterine volume and chronologic and gynecologic age (expressed as number of months from menarche) and hormone values are determined by linear regression analysis.

Results

In general, the uterus showed typical, mature, pear-shaped morphology with a corpus/cervix ratio greater than 1. Table I shows that uterine diameters slowly increased in the years after menarche. Significant differences disappeared around the third or fourth gynecologic year, but mean diameters did not reach the average control value by the sixth year.

A positive correlation between uterine volume and gynecologic age ($r = 0.24$; $p < 0.05$) was found. A positive correlation was also seen between uterine volume and chronologic age ($r = 0.23$; $p < 0.05$).

Fig. 1 shows mean values (±SD) of uterine volume grouped according to postmenarchal and chronologic ages in adolescents and sexually mature control subjects. Mean uterine volume increased gradually from the first to the sixth year after menarche when its value was still lower, albeit not significantly different from that of adult control subjects. Regarding chronologic age, uterine volume increased progressively starting from age 13 years onward. Significant differences between adolescent and control values disappeared at age 18 years.

Uterine volume increased in correlation with estradiol levels in both the follicular and premenstrual phases ($r = 0.22$; $p < 0.05$; $r = 0.25$; $p < 0.05$, respectively). Dehydroepiandrosterone ($r = 0.22$; $p < 0.05$) and dehydroepiandrosterone sulfate ($r = 0.22$; $p < 0.05$) correlated with uterine volume during the follicular phase.

No correlations were found between uterine volume, the other hormones, bone age, weight, height, and ovarian volume. Furthermore, uterine volume does not change with the frequency of ovulation (i.e., the number of ovulations in six months) nor with the frequency of menstrual bleedings. The ovarian/uterine ratio progressively decreased in the first 6 postmenarchal years, but at the sixth year it was still higher than that found in adults.

Comment

The uterus grows progressively during fetal life.[9] After birth, uterine volume is relatively high, longer, and thicker than the prepubertal uterus and shows endometrial and myometrial characteristics very similar to those of adults[10]

After the first weeks, uterus size regresses,[11] probably because of the withdrawal of maternal hormone stimulation. During childhood the uterus shows no changes in size and shape until the age of 7 years.[12] From this age onward, uterine volume increases progressively at a slow rate before the appearance of secondary sexual characteristics, whereas a sharp acceleration is seen

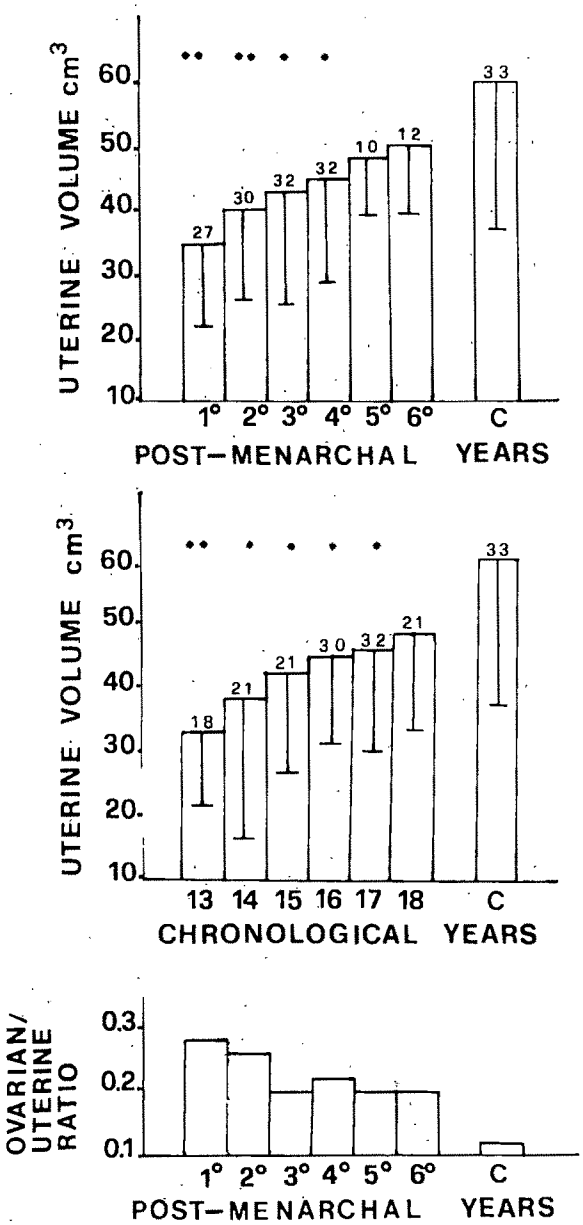

Fig. 1. Mean values (±SD) of uterine volume grouped according to gynecologic and chronologic years in adolescents. Sexually mature controls *(C)* are reported. Number of subjects is reported in each column. $*p < 0.01$; $**p < 0.001$, with respect to control uterine volume. *Bottom panel:* Mean ovarian/uterine ratio in adolescent girls during gynecologic years and sexually mature controls *(C)*.

during puberty, which has a good correlation with Tanner stages,[7] age, weight, height, and estradiol levels,[12] and the most dramatic changes between stage 3 and 4 of breast development.

This study documents thtat after menarche, the uterus continues to grow, even after the almost-complete development of the secondary sexual characteristics. Menarche is a critical step toward the development of the whole reproductive system, especially of the uterus, which assumes a new function. After menarche, uterine growth rate slows and gradually tends to take on the adult size. However, normal adult values are not attained even by the sixth gynecologic year, which shows that full development of this reproductive organ takes even more time, although adult morphology and corpus/cervix ratio are already achieved by menarche.

Comparison between our data and values reported by other authors in postpubertal girls is difficult because of the low number of subjects in those studies that did not group adolescents into postmenarchal years. However, the mean uterine length found by Sample et al.[13] in a group of 25 girls ranging in age from 13 to 20 years and the mean uterine longitudinal diameter and volume reported by Ivarsson et al.[7] at 13 and 17 years correspond fairly closely to our values.

We previously demonstrated[14] the dynamic postmenarchal behavior of many reproductive parameters. Among the increasing reproductive hormones, estradiol seems to be the main agent for uterine growth in this study. On the other hand, other reproductive parameters, such as the frequency of menstrual bleeding and that of ovulation and progesterone levels, do not appear related to uterine size and growth rate.

Height and weight correlate with uterine volume before menarche but not afterward, since at this age they have nearly exhausted the developmental changes and vary independent of growth factors. The adrenal steroids dehydroepiandrosterone and dehydroepiandrosterone sulfate, which are faithful indexes of biologic maturation, continue to increase during adolescence,[14] and interestingly, they correlated with uterine development in this study. The low correlation coefficients that we found between uterine increases and hormone and age changes show that other influences are probably mainly responsible for uterine size variations during the first postmenarchal years.

The finding of a still small uterus during adolescence may have reproductive implications. The lack of complete genital tract maturity might partly account for problems such as preterm labor, preeclampsia, and small-for–gestational age infants; these problems are not uncommon in adolescence.[15]

Our data show an ovarian/uterine ratio that decreases with increasing gynecologic age. The mean value at the first gynecologic year is very similar to that found in the polycystic ovary syndrome,[16] probably because unlike the uterus, the ovaries seem to have already reached complete growth at menarche.[6] Furthermore, their volume often exceeds the adult value and needs a reduction in size to reach the final maturational step.[6] Thus ovarian development frequently follows a biphasic process in adolescence, first increasing up to menarche and afterward decreasing in size to reach the

adult pattern. The second part of the process is associated with and caused by an increase in the frequency of ovulation.[6] We previously reported that the reproductive endocrine and ovarian pattern of the first gynecologic years is often similar to that of polycystic ovary syndrome.[6] The ovarian/uterine ratio we found in this study further documents that the reproductive maturation in adolescence often includes polycystic ovary syndrome–like features that tend to disappear with the progression of postmenarcheal development.

Leiomyoma of the ovary with ascites and hydrothorax

Jonathan J. Nicoll, MA, and Peter J. Cox, MS
London, England

A case is described in which a leiomyoma of the ovary was accompanied by hydrothorax. There was no reaccumulation of fluid after oophorectomy. (Am J Obstet Gynecol 1989;161:177-8.)

Key words: Ovarian leiomyoma, hydrothorax

Leiomyoma arising primarily in the ovary is rare. We describe a case in which such a tumor was associated with ascites and hydrothorax, an association that has not previously been reported.

Case report

A 33-year-old woman who had been treated for supradiaphragmatic Hodgkin's disease 4 years previously complained of lower abdominal pain, chest discomfort, and shortness of breath. Examination revealed a large pelvic mass and signs of a right-sided pleural effusion. Ultrasonography and computed tomography confirmed the presence of ascites and a pelvic mass, but failed to demonstrate the organ of origin of the tumor. A chest radiograph showed a large right-sided pleural effusion.

Two liters of straw-colored fluid was aspirated from the right chest. Cytologic examination of the fluid showed mononuclear and binuclear cells with prominent nucleoli that were highly suggestive of Hodgkin's disease. Treatment was started with standard combination chemotherapy for Hodgkin's disease but there was reaccumulation of pleural fluid.

After three cycles of chemotherapy a large right-sided pleural effusion still remained and the pelvic mass was larger. It was decided to proceed to laparotomy,

which was performed with an intercostal drain in situ.

At operation a 9 cm spherical tumor was found arising from the right ovary. All other organs were normal; there was no lymphadenopathy.

Right oophorectomy was performed without difficulty. Histologic examination of the specimen showed a benign leiomyoma of the ovary that was well circumscribed and composed of spindle-shaped cells with eosinophilic cytoplasm and blunt-ended nuclei. Myofibrils were visible on staining with phosphotungstic acid–hematoxylin.

The day after operation the chest radiograph was normal and the drain was removed. No further chemotherapy was given. Two years later the patient remained well with no abnormal physical findings and a normal chest radiograph.

Comment

Leiomyoma of the ovary was originally described by Sangalli in 1862, and the literature on the subject was well reviewed in 1972.[1]; at that time 28 cases had been reported. The well-recognized association between ovarian fibroma and hydrothorax (eponymously known as Meigs' syndrome) was described in 1937.[2] All seven cases in Meigs' original report had fibromas or fibromyomas. We believe our case is the first reported case in which hydrothorax was found with a leiomyoma of the ovary.

Although our patient had a history of Hodgkin's disease, the fact that pleural fluid reaccumulated rapidly despite combination chemotherapy but disappeared completely after removal of the ovarian tumor strongly suggests that the hydrothorax was caused by the tumor. We initially thought the hydrothorax was a result of a recurrence of Hodgkin's disease, but subsequent events have led us to believe that the lymphoma has not reactivated and that the cytologic appearances were caused by the presence of reactive mesothelial cells.

We thank Dr. K. A. Newton and Mr. J. M. Thomas for permission to publish this case.

Individual growth curve standards in twins: Prediction of third-trimester growth and birth characteristics

Theodor Stefos, MD,[a] Russell L. Deter, MD,[a] Reba M. Hill, MD,[b] and Nicolas V. Simon, MD[c]

Houston, Texas, and York, Pennsylvania

The ability of Rossavik growth models, determined from measurements obtained before 24 weeks, to predict third-trimester growth and birth characteristics in normally growing twins has been investigated. Third-trimester values for head circumference, abdominal circumference, and femur diaphysis length were predicted with an accuracy of ±6% to 9% (95% to 98% of percent deviations). For thigh circumference and estimated weight, the comparable values were ±15% and ±16%, respectively. The head circumference at birth was predicted without bias; the random error was approximately ±5% (94% of percent differences). Weight, abdominal circumference, and thigh circumference were systematically overestimated (3.1%, 14.9%, and 11.3%, respectively) as a result of differences in prenatal and postnatal measurement procedures. After correction for systematic errors, these parameters could be predicted with random errors of −11.5% to 7.2% (weight), −12.8% to 5.4% (abdominal circumference), and −15.3% to 10.0% (thigh circumference). Growth Potential Realization Index values were found to have means of approximately 100% and ranges from 91% to 118%. These results are similar to those for singletons and indicate that *individual* assessment of growth in twins can be carried out with the same methods used for singletons. (Am J Obstet Gynecol 1989;161:179-83.)

Key words: Twins, growth prediction, Rossavik model

Twin pregnancies represent a high-risk condition in which growth problems frequently occur. Previous studies have evaluated twin growth through comparisons with the growth of singletons[1-5] by establishing specific growth standards for twins[3, 4, 6] or from the assessment of differences in the growth of two twin fetuses.[4-10] Growth studies concerned with comparisons with singletons and the establishment of twin growth standards[1-6] have used cross-sectional analytic methods even though serial measurements were included in the data sets ("mixed" type of growth study). This approach does not provide valid estimates of variability and does not account for differences in fetal growth potential.[11] Assessment of differences in growth between twins has also failed to account for differences in growth potential, has frequently used arbitrary criteria to determine what represents a significant growth difference, and has not provided a means for detecting a major loss of maternal support that could adversely affect both twins equally.

As with the growth of singletons, the problems associated with the evaluation of twin growth can be eliminated by the use of *individual growth curve standards*.[11] This requires specification of Rossavik growth models based on growth curves obtained in the second trimester[11, 12] Recent studies (Stefos and Deter. Unpublished data.) have shown that second-trimester growth in twins is similar to that in singletons, and no statistically significant effect of zygocity on growth could be detected. These results indicated that during the second trimester, the growth of twins could be treated like the growth of two singletons in the same mother. Such a concept of twin growth provides justification for the use of the Rossavik growth model specification procedures previously developed for singletons.[12] This article presents the results of our study of the use of Rossavik growth models in predicting growth after 24 weeks, menstrual age, and the birth characteristics of normally growing twins.

Material and methods

Sample. This study was carried out with data collected from 16 twin fetuses in 11 pregnancies. The patients studied were primarily middle-class whites (10 of 11 patients, one Hispanic) from the Houston area. The maternal age ranged from 23 to 32 years (mean, 29 years). These patients delivered fetuses between 33 and 39 weeks, menstrual age (mean [±SD]: 36.9 [±1.7] weeks), and comprehensive pediatric assessment (within 24 hours of delivery) revealed no evidence

*Data for singletons previously published[12] and presented here for comparison with those for twins.

†The values in parentheses indicate the proportion of the percent deviations after 24 weeks (twins) or 26 weeks (singletons) included in the range.

of growth abnormalities or congenital anomalies. Birth characteristics such as weight (mean [±SD]: 2904 [±350] gm) length (mean [±SD]: 48.8 ± 2.0 cm), and head circumference (mean [±SD]: 33.5 [±1.1] cm) were within the normal ranges for singletons determined by Usher and McLean.[13] In 14 twin fetuses abdominal circumference (mean [±SD]: 29.6 [±2.1] cm) and thigh circumference (mean [±SD]: 14.1 [±1.1] cm) measurements were also available and within the normal ranges for singletons.[13] Nutrition score values, a measure of subcutaneous tissue, were also available for 14 twin fetuses and were above 12 (range, 13 to 16) for all but one fetus (8.5), values associated with well-nourished infants. Growth Potential Realization Index values were within the normal ranges of singletons[14] for weight and head circumference in all but two of the twin fetuses. Ten of 14 twin fetuses had abdominal circumference Growth Potential Realization Index values within the singleton normal range, whereas comparable numbers were nine of 14 for thigh circumference. There were eight male and eight female twin fetuses in this sample.

Fetal age determination. Fetal age determination was based on the first day of the last menstrual period, which was confirmed by first-trimester and early second-trimester ultrasound examinations (crown-rump length, biparietal diameter, and femur diaphysis length measurements)[15] in 13 of 16 fetuses. In three fetuses, fetal age estimates determined by ultrasound examination and last menstrual period did not agree. The ultrasound age estimates (based on early second-trimester scans) were used in these cases. Birth ages derived from obstetric data were similar to those determined postnatally by either the Dubowitz or Ballard methods (mean differences [±SD]: 1.0 [±1.1] weeks and 1.4 [±1.4] weeks, respectively) for the 14 twin fetuses in whom estimation of birth age with obstetric and pediatric methods was carried out. However, the differences in age estimates were significantly different from zero (t test; $p < 0.05$).

Ultrasound examinations. The ultrasound examinations were carried out at 2-week intervals from 15 weeks, menstrual age (initial scan [mean ± SD]: 14.7 ± 1.7 weeks), to 36 weeks (last scan [mean ± SD]: 35.9 ± 1.5 weeks). The interval between the last scan and delivery was (mean ± SD) 1.0 ± 0.5 week. Each twin was identified at each examination by its position in the uterus, its size, or its sex. Measurements of the biparietal diameter, the long and short axes of the head and abdominal profiles, as well as measurements of the femur diaphysis length and thigh circumference, were obtained at each examination for each twin with use of procedures described in previous publications.[16, 17] The head and abdominal circumferences were calculated from the corresponding diameters,[17] and the estimated weight was determined from values of the head and abdominal cubes as previously described.[18]

Evaluation of placentas and fetal membranes. Examination[19] of the placentas and fetal membranes in these twin pregnancies indicated that eight of the fetuses were from dizygotic pregnancies and eight were from monozygotic pregnancies.

Data analysis. Values for start points and the coefficients k, c, and s of the Rossavik growth model [$P = c(t)^{k + s(t)}$] were obtained, as indicated in a previous publication,[12] for the head circumference, abdominal circumference, femur diaphysis length, thigh circumference, and head and abdominal cubes from measurements obtained before 24 weeks' menstrual age. The models specified by these data were used to predict appropriate values for each parameter during the third trimester and at birth for head circumference, abdominal circumference, thigh circumference, and estimated weight. Birth predictions for fetuses delivering after 38

§Significantly different from zero ($p < 0.05$).

weeks (six of 16) were those for 38 weeks, since no growth after 38 was assumed.[14]

The ability of models derived from data obtained before 24 weeks, menstrual age, to predict fetal growth in the third trimester was evaluated by comparing actual measurements at various time points to predicted values and expressing the differences as a percentage of the predicted values (percent deviations). Means (systematic prediction errors) and ranges (random prediction errors) for the percent deviations were determined.

To evaluate the ability of these models to predict birth characteristics, predicted birth head circumference, abdominal circumference, thigh circumference, and estimated weight values were compared with actual measurements at birth, and the differences were expressed as a percentage of the actual measurements (percent differences). The means and standard deviations of these percent differences were determined, and the mean values were compared with zero by Student *t* test to identify systematic errors. The relationships between the percent difference and birth age for each of the four parameters studied were evaluated by linear regression analysis.

To provide standards for assessing pregnancy outcome on an *individual* basis, Growth Potential Realization Index (GPRI) values were calculated for each parameter in each twin fetus.[14] Growth Potential Realization Index values are determined by means of the following equation:

$$\text{GPRI} = \frac{\text{Actual measurement at birth}}{\text{Predicted measurement at birth}} \times 100$$

For parameters in which a systematic difference between the predicted and actual birth measurements was found, predicted birth measurements corrected for the systematic error were used in the calculation of Growth Potential Realization Index values.[14] Growth Potential Realization Index values take into account differences in genetic growth potential.

Results

Prediction of growth in the third trimester. As shown in Table I, systematic errors in predicting third-trimester growth were small for all parameters (−2.0% to 2.1%). The random prediction errors were also small (±6% to 9%) for the one-dimensional parameters (head circumference, abdominal circumference, and femur diaphysis length) except for thigh circumference [±15%]). For estimated weight, a three-dimensional parameter, the random prediction error, was smaller (±16%) than would be expected (±21% to 22%) on the basis of random prediction errors observed for one-dimensional parameters.

Prediction of birth characteristics. Although based on models derived from data obtained 9 to 15 weeks before delivery (or more), the Rossavik growth models specified in this investigation predicted the birth characteristics of twin fetuses well. No systematic prediction errors were found for head circumference, but the weight, abdominal circumference, and thigh circumference were overestimated (3.1%, 14.7%, and 13.1%, respectively). As can be seen in Table II, such overestimations have also been observed in singleton fetuses for abdominal circumference and thigh circumference. These errors can be explained primarily on the basis of differences in the prenatal and postnatal techniques for obtaining measurements of these three parameters.[14, 18] Correction for these systematic errors (correction factors for weight, abdominal circumference, and thigh circumference: 0.969, 0.851, and 0.887, respectively[14]) resulted in random prediction errors that ranged (100% of percent differences) from −11.5% to 7.2% for weight, −12.8% to 5.4% for ab-

Table III. Growth potential realization index values in normal twin and singleton fetuses

‡Not significantly different from 100% ($p > 0.05$).

dominal circumference, and −15.3% to 10.0% for thigh circumference.

Linear regression analysis failed to reveal any relationship between the percent difference and birth age over the 33- to 39-week interval in which delivery of these twin fetuses occurred. The respective R^2 values were 1.8% for head circumference, 0.0% for abdominal circumference, 0.0% for thigh circumference, and 0.0% for weight.

Growth Potential Realization Index. Table III presents the means and ranges of the Growth Potential Realization Index for the four parameters (head circumference, abdominal circumference, thigh circumference, and weight) evaluated postnatally in these twin fetuses. Corrected predicted values for weight, abdominal circumference, and thigh circumference were used in these calculations. The mean Growth Potential Realization Index values were not significantly different from 100%, and individual values ranged from 91% and 118% depending on the parameter being studied. The lowest variability in Growth Potential Realization Index values was seen with the head circumference (94% to 102%).

Comment

In evaluating the performance of Rossavik models in predicting growth in twins, it is essential that such assessment be carried out under conditions in which poor model performance can be detected. Because evaluation of growth predictions was based on the degree of agreement between actual measurements and predicted values, deviations caused by abnormal growth must be excluded if at all possible. This is a particular problem with twins, since twin fetuses have a much higher incidence of growth abnormalities and tend to deliver prematurely. The twins studied in this investigation were close to term in most cases (birth age: 36.9 [± 1.7 SD] weeks), and a variety of postnatal measurements were within normal ranges for singletons. In addition, most postnatal measurements were in agreement with predicted values if the criteria developed for singletons (Growth Potential Realization Index values [see Table III]) were used. These data strongly support the conclusion that growth in these twins was normal, and thus significant deviations from predicted values would have to be the result of poor model performance and not growth abnormalities.

Rossavik model performance in twins can best be judged by comparison with that seen in singletons (Tables I to III). With the exception of a small systematic overestimation of the abdominal circumference and femur diaphysis length values, the ability of Rossavik models to predict growth in the third trimester was essentially the same as that seen in singletons for all five parameters. The ability to predict birth characteristics was also similar in twins and singletons with the exception of the thigh circumference and weight, in which greater systematic overestimation was seen in twins. The reason for these differences is currently unknown, but the difference for weight was small, and specification of Rossavik models for the thigh circumference is difficult because of measurement problems in the second trimester that require the use of a fixed start point.[20] Leg position may also affect this measurement.[14]

With respect to Growth Potential Realization Index values, mean values were close to 100% for all parameters in both twins and singletons, and the ranges were similar in both groups for head circumference and weight. A small shift to higher values was seen with abdominal circumference and thigh circumference. However, these two parameters required greater correction of predicted values for systematic overestimations, and the correction factors for twins were based on fewer measurements than those for singletons. Also, the 100% range is presented for twins to compensate for the smaller number of values available, whereas the 95% range is given for singletons. In any case, there

does not appear to be major differences between twins and singletons with respect to Growth Potential Realization Index values.

Since use of Rossavik growth models *individualizes* the assessment of growth, no direct comparisons can be made with previous cross-sectional (actually "mixed") growth studies in twins. However, our results are consistent with those indicating similarities in the normal growth of twins and singletons[4, 5] and suggest that those investigations reporting differences[1-3] may have included normally and abnormally growing twins in the sample studied. The postnatal evaluation of twin fetuses in some investigations has been limited to birth weight assessment[1, 5] or not reported.[2] More extensive evaluation of the newborn twin fetuses (weight, head circumference, and length) indicated no significant differences in head circumference and length between twins and singletons, but the birth weights were significantly lower in twins.[3, 4]

The results of these investigations indicate that *individualized* assessment is as effective with twins as it is with singletons. Subsequent publications will use this approach in the detection, characterization, and establishment of relationships in abnormally growing twins.

Effect of birth weight, race, and sex on survival of low-birth-weight infants in neonatal intensive care

Michael B. Resnick, EdD,[a] Randy L. Carter, PhD,[b] Mario Ariet, PhD,[c] Richard L. Bucciarelli, MD,[a] Janet H. Evans, MSPA,[d] Robert R. Furlough, PhD,[d] William W. Ausbon, MD,[d] and John S. Curran, MD[e]

Gainesville, Tallahassee, and Tampa, Florida

Survival for low-birth-weight infants has traditionally been analyzed by birth weight categories spanning considerable ranges of weight. We developed a finer description of survival rates to allow estimation of survival percentages for infants of any specific birth weight between 500 and 2500 gm. Our sample consisted of 16,183 infants treated in tertiary neonatal intensive care between 1980 and 1987. Their survival data were analyzed by 50 gm increments between 500 and 2500 gm, and a continuous survival curve was constructed by log linear regression methods. Mortality differences between males and females and blacks and whites were analyzed. Survival for females was higher than males between 500 and 1500 gm and higher for blacks than whites between 650 and 1500 gm. Between 1500 and 2500 gm, no significant effects of birth weight, race, or sex were observed, with survival remaining stable at approximately 95% across all combinations of variables. (AM J OBSTET GYNECOL 1989;161:184-7.)

Key words: Neonatal survival, neonatal mortality, low birth weight, prematurity, neonatal intensive care

For two decades research has verified that low birth weight is the major contributor to infant mortality in the United States.[1-7] Traditionally, survival for low-birth-weight infants has been analyzed using arbitrarily defined categories—most often, <1000 gm, 1000 to 1500 gm, and 1500 to 2500 gm. The creation of artificial groups spanning considerable birth weight ranges has been necessitated by the limited sample sizes available to most researchers. National statistics on low-birth-weight infants have employed even cruder birth weight categories, usually restricted to <1500 gm and 1500 to 2500 gm.[2,8]

The purpose of our research was to analyze neonatal survival statistics for low-birth-weight infants admitted to the State of Florida's Perinatal Intensive Care Program for the period 1980 to 1987 (a total of 16,183 infants weighing 500 to 2500 gm at birth). The data were analyzed by 50 gm increments to yield a more precise description of survival rates than any currently available. We developed a statistical model to estimate the probability of survival for any specific birth weight.

The mortality differences between males and females, and blacks and whites, were an additional focus of study. The survival edge of girls over boys has long been known, but its magnitude in low-birth-weight infants has not been documented. The mortality of black neonates has been reported as 20 per 1000 live births, compared to only 10 per 1000 for whites.[9] Consequently, we used the same 50-gm increments described above to analyze survival data by race and sex.

Material and methods

Patients. The low-birth-weight infants whose data were used for the study received tertiary neonatal intensive care in the State of Florida's Perinatal Intensive Care Program from July 1980 through June 1987. During this period approximately 27,000 infants were admitted to the Program's 10 neonatal intensive care units; approximately two thirds of them were inborn and the remainder were transported. Of these, 16,183 infants weighed <2500 gm at birth and were included in the study: 7231 weighed 500 to 1500 gm and 8952 weighed 1500 to 2500 gm. To be counted as a survivor, an infant had to survive the period of neonatal intensive care and subsequent hospitalization in a step-down facility or in the referring hospital. Descriptive statistics appear in Table I.

Statistical methods. Observed survival rates were analyzed with log linear regression models. These models

Major surgery	7	4
Assisted ventilation	63	33

were chosen because curves constructed with log linear regression methods have been demonstrated to fit survival data better than those constructed with logistic regression.[10] A model was used to fit curves to the observed proportions of survival for 50 gm increments from 500 to 1500 gm and another (similar) model to fit survival curves for the increments from 1500 to 2500 gm. These models were specified to yield a survival probability curve for each race-by-sex combination: black females, black males, white females, and white males.

Results

The data demonstrated significant effects of birth weight on survival from 500 to 1500 gm, with the probability of survival increasing until 1500 gm was reached (Fig. 1). Sex and race also affected survival significantly (Fig. 2). At any given birth weight up to 1500 gm, survival rates were better for females than for males, reaching a maximum difference of 10 to 14 percentage points between 500 and 1100 gm. A similar pattern emerged for blacks and whites, although white survival was greater at the lowest birth weights (500 to 650 gm). Improved survival rates for black infants emerged at 650 gm, with a maximum difference of 6 to 7 percentage points between blacks and whites reached between 800 and 1250 gm. The differences between males and females were the same for blacks and whites over all birth weights.

Analyses of data for infants who were inborn versus those who were transported showed no significant survival differences. Furthermore, no statistically

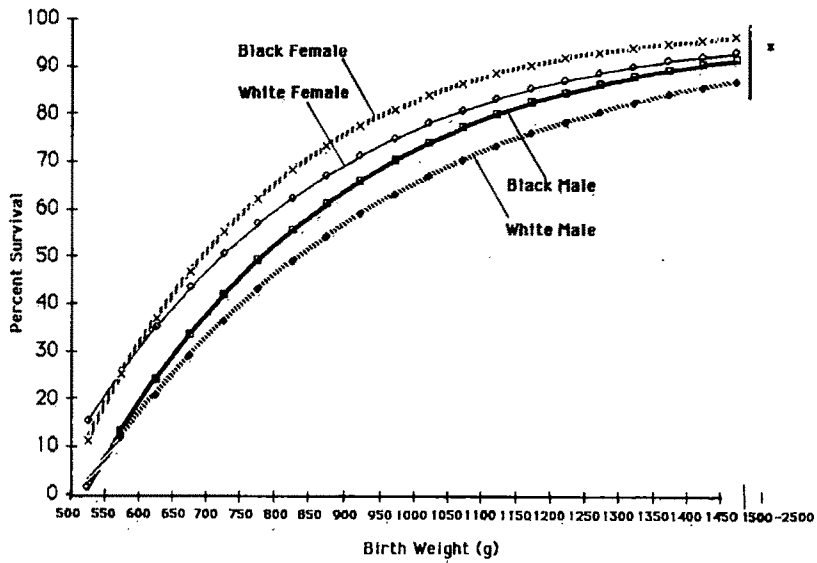

Fig. 2. Comparison of survival data for low-birth-weight infants by race, sex, and birth weight, with 50 gm increments from 500 to 1500 gm. Each point is plotted midway through its birth weight interval. For example, the point for infants weighing 500 to 550 gm is plotted at 525 gm. A measure of goodness of fit of these curves, analogous to the usual R^2 coefficient,[11] was 0.97.

Table II. Subsample size for each birth weight category, 500 to 1500 gm

Category No.	*Birth weight category (gm)*	*Sample size (N)*
1	500-550	132
2	550-600	198
3	600-650	229
4	650-700	274
5	700-750	317
6	750-800	344
7	800-850	323
8	850-900	349
9	900-950	354
10	950-1000	493
11	1000-1050	369
12	1050-1100	425
13	1100-1150	387
14	1150-1200	472
15	1200-1250	421
16	1250-1300	486
17	1300-1350	410
18	1350-1400	549
19	1400-1450	506
20	1450-1500	565

significant interactions were found between inborn/transport status and race, sex, or birth weight category.

Infants weighing 1500 to 2500 gm at birth were not significantly affected by birth weight, race, or sex, or their interactions. Survival in these infants was nearly constant (approximately 94.5%) across all combinations of variables.

Equation for probability of survival. Equations were derived for the fitted model for each race-by-sex combination to predict probability of survival for infants weighing ≤1500 gm at birth.

Black females:
$$\text{Log } (P_m) = 0.0548 - 0.1702 \text{ BWC}$$
Black males:
$$\text{Log } (P_m) = 0.1293 - 0.1348 \text{ BWC}$$
White females:
$$\text{Log } (P_m) = -0.0261 - 0.1352 \text{ BWC}$$
White males:
$$\text{Log } (P_m) = 0.0484 - 0.1098 \text{ BWC}$$

where BWC = birth weight group (for example, 1 = 500 to 550 gm, 2 = 550 to 600 gm, etc., to 20 = 1450 to 1500 gm) (Table II) and P_m = probability of death before hospital discharge.

$$\text{Probability of survival} = 1 - e^{\log(P_m)}$$

Examples. A black female weighing 1215 gm is admitted to the neonatal intensive care unit on the same day as a white male weighing 1240 gm. Their probabilities of survival are calculated below:

Black female: $\text{Log } (P_m) = 0.0548 - 0.1702 \times 15$
$= 0.0548 - 2.5531$
$= -2.4983$
Probability of survival $= 1 - e^{\log (P_m)}$
$= 1 - e^{(-2.4983)}$
$= 0.92$

White male: $\text{Log } (P_m) = 0.0484 - 0.1098 \times 15$
$= 0.0484 - 1.6464$
$= -1.5980$
Probability of survival $= 1 - e^{\log(P_m)}$
$= 1 - e^{(-1.5980)}$
$= 0.80$

Comment

Previous analyses of neonatal survival that were based on birth weight used broad, arbitrarily defined groups, such as 750 to 1000 gm, 1000 to 1500 gm, etc. Although these birth weight ranges have been dictated by some clinical rationale, their predictive value has been limited by the obvious differences in survival outlook for infants at the high and low ends of the ranges. In the 1000 to 1500 gm category, for example, an infant weighing 1000 gm has about a 75% chance of surviving, whereas one weighing 1500 gm has almost a 95% chance. The continuous curves produced by this statistical model permit estimation of the probability of survival for infants with birth weights between 500 and 2500 gm. If the curves are used to estimate survival probability prenatally with ultrasonographic data, possible measurement error must be taken into consideration.

A refinement of our model is its breakdown by sex and race. This division is critical to the accuracy of the model as a predictive tool. Our continuous curves describing neonatal survival demonstrate that race and sex effects are important. For example, at 1025 gm, 68% of white males survive compared with 84% of black females. The accuracy of survival estimates improves with the use of race-by-sex descriptors, i.e., black female, black male, white female, and white male.

The differences in infant mortality between blacks and whites have gained increasing attention.[1, 9] Data show that infant deaths are twice as high among blacks (18 deaths per 1000 live births, compared with only 9 per 1000 births for whites).[8] During the neonatal period, mortality figures are approximately 12 deaths per 1000 for blacks and 7 deaths per 1000 for whites.[12] The latter discrepancy can be explained primarily by the fact that blacks have twice the incidence of low birth weight as whites, a condition that carries a high mortality. Black infants weighing <2500 gm at birth have been found to have higher survival rates than white infants in this weight range.[12] In our study survival of black infants between 650 and 1500 gm was consistently higher than that of whites, reaching a difference of 6 to 7 percentage points between 800 and 1250 gm. Consequently, further reductions in neonatal mortality for the black population will probably depend on programs that lower the incidence of prematurity.[13, 14]

Race and sex had no significant effects on survival for infants weighing >1500 gm at birth. At this weight, the survival curves for black females, black males, white females, and white males admitted to the neonatal intensive care unit converged to the same ceiling, approximately 95% survival. Increases in birth weight >1500 gm had no significant effect on survival. These results suggest that the conventional clustering of infants weighing 1500 to 2500 gm into a single birth weight category is useful prognostically for babies in the neonatal intensive care unit. However, for infants weighing <1500 gm at birth a more detailed description by race, sex, and birth weight is desirable.

We thank Barbara G. Cox, Biomedical Editor, for her assistance in the preparation of the paper.

Effects of maternal hyperoxia on the biophysical assessment of fetuses with suspected intrauterine growth retardation

David A. Ruedrich, MD, Lawrence D. Devoe, MD, and Nancy Searle, BA
Augusta, Georgia

Fifty-two third-trimester fetuses with suspected intrauterine growth retardation were studied by means of a computer-assisted biophysical assessment scheme, which used maternal hyperoxia as a diagnostic probe. Biophysical data examined included percentage of time spent in breathing, mean breath rate, and percentage of time spent in body movement during a 90-minute observation: 30-minute baseline, 15-minute hyperoxia, and 45-minute posthyperoxia. Mean baseline movement in fetuses found as neonates to have intrauterine growth retardation ($N = 18$) was significantly lower than that of normal fetuses ($N = 34$). Fetal body movements and breathing movements increased significantly after hyperoxia in the intrauterine growth retardation group but not in the normal group. Increases of more than 75% over baseline for fetal breathing and more than 250% over baseline for fetal body movements yielded a sensitivity of 56%, specificity of 94%, positive predicative value of 83%, and negative predicative value of 80%. Maternal hyperoxia during biophysical testing may improve the accuracy of detecting intrauterine growth retardation. (Am J Obstet Gynecol 1989;161:188-92.)

Key words: Intrauterine growth retardation, fetal breathing, fetal movement, maternal hyperoxia

Biophysical testing, which includes fetal breathing movements and gross body movements, has been used to assess the high-risk fetus.[1] Alterations in fetal breathing or body movement patterns may improve the detection of intrauterine compromise. Intrauterine growth retardation (IUGR) has been associated with decreased levels of fetal breathing activity, which may be related to fetal hypoxia stemming from placental insufficiency.[2] Earlier reports concerning biophysical activities in growth-retarded fetuses have provided inconsistent data. Ritchie and Lakhania[3] proposed that maternal oxygen administration, which resulted in maternal hyperoxia, might enhance breathing activity of growth-retarded fetuses. Maternal hyperoxia has been shown to increase fetal capillary P_{O_2} during the intrapartum period[4]; however, normal term fetuses do not exhibit significant alterations in fetal breathing or movement patterns after maternal hyperoxia.[5]

Because IUGR is a significant perinatal problem, accurate detection of this condition is important for antenatal management. The purpose of this study was to determine whether growth-retarded fetuses demonstrated predictable alterations in their biophysical behavior after maternal hyperoxia. If diagnostic thresholds for such alterations in breathing or body movement incidence existed, discrimination of growth-retarded fetuses from normal fetuses might then be improved.

Material and methods

Fifty-two third-trimester fetuses suspected of IUGR and whose mothers received care at the Medical College of Georgia Hospital and Clinics were included in the study. Abnormal ultrasonographic growth curves, head-to-abdomen circumference ratios, or estimated fetal weight below the tenth percentile for gestational age served as a basis for inclusion in this study. All fetuses had gestational age previously established by clinical dating with ultrasonographic corroboration before the twentieth week of gestation, were singletons, and had no congenital anomalies. No pregnancy was complicated by glucose intolerance.

Informed consent was obtained from each mother before the performance of each study (investigation protocol approved by the Human Assurance Review Committee). Each study was conducted under standardized conditions that began 2 hours postprandial, between 8:30 and 10:30 AM. Smoking was not permitted for 12 hours before the study, and subjects abstained from central nervous system depressants or stimulants. Observations were made in a quiet room with the patient in a semirecumbent position. Each study lasted 90 minutes: a 30-minute baseline control period, a 15-minute period of maternal hyperoxia, and a 45-minute posthyperoxia observation period. Mater-

1 min Apgar	7.67 ± 1.86	7.82 ± 1.40	NS
5 min Apgar	8.89 ± 0.31	8.94 ± 0.42	NS
$TcPO_2$ (mm Hg; 50% FiO_2)	114 ± 20.5	116 ± 17.6	NS

Results presented as means ± standard deviations.
EGA, Estimated gestational age; *$TcPO_2$*, transcutaneous oxygen pressure; *FiO_2*, fraction of inspired oxygen.

nal hyperoxia was established by means of a 50% concentration of inspired oxygen delivered by Venturi mask and documented with a Novametrix 818 continuous transcutaneous oxygen ($TcPO_2$) monitor. With this technique, maternal hyperoxia was promptly established in each case within 5 minutes of oxygen administration.

Observation of fetal breathing and movement was performed with an ATL 4000 linear array real-time ultrasound scanner operating at 3.5 MHz. A sagittal view of the fetal thorax and abdomen was obtained for optimal observation of fetal breathing and trunk flexion-extension movements. These data were entered via a remote event marker into an IBM XT microcomputer (512 K RAM) with specially designed software. This system has been previously described.[6]

Each infant was evaluated at delivery by a neonatologist for the presence of IUGR. Infants were grouped into IUGR or normal growth categories on the basis of an institutional nomogram, with the tenth percentile for weight according to gestational age as the discrimination point. Apgar scored at 1 and 5 minutes and abnormal intrapartum and neonatal outcomes were recorded.

Analysis of fetal breathing and body movement incidences (percentage of time spent in activity) and fetal breathing rates were performed off-line for each 15-minute interval of study. The two 15-minute baseline (30 minutes total) segments were grouped together for purposes of comparison. Statistical analysis used included Student *t* tests for comparing IUGR with normal fetuses and analysis of variance to examine alterations

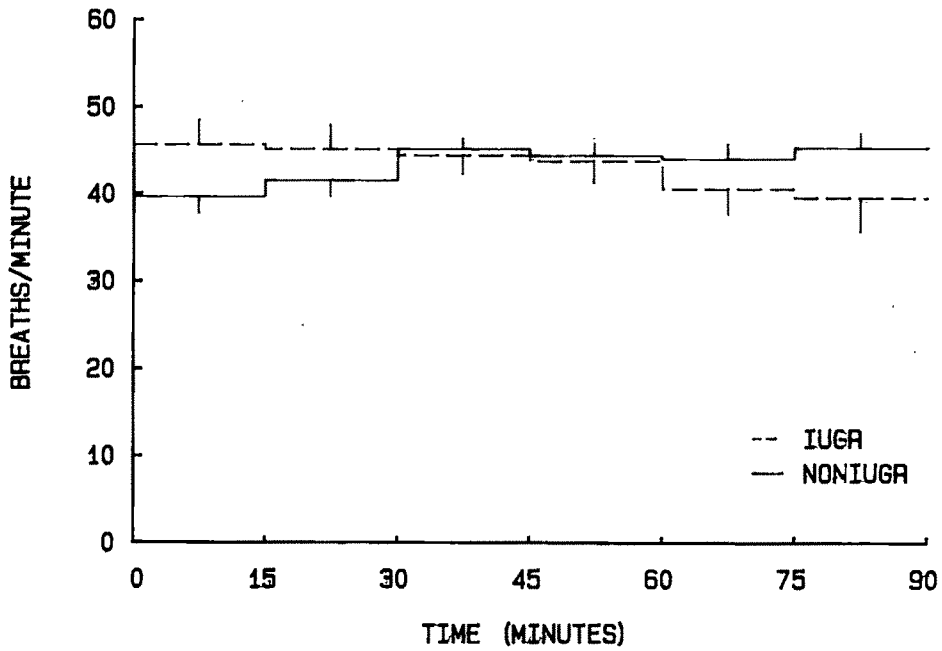

Fig. 2. Fetal breath rates before, during, and after maternal hyperoxia (given at time = 30 minutes). No significant alterations were observed.

of biophysical parameters within each group. A p value of <0.05 was considered significant.

Results

Eighteen of the 52 fetuses (34.6%) were growth retarded according to institutional criteria. Characteristics concerning gestational age at the time of study and delivery, as well as birth weight and Apgar scores for IUGR and normal fetuses, are shown in Table I. Both groups were similar in all characteristics except for mean birth weight, which was significantly lower, as expected, in the IUGR group. No perinatal deaths or significant neonatal morbidity occurred in either group.

Observation of fetal breathing movements yielded similar mean incidences of breathing activity for both groups during the baseline period. Mean fetal breathing movement incidence appeared to increase in both groups during the hyperoxia interval, but was significantly elevated over baseline values ($p < 0.05$) in the IUGR group alone (Fig. 1). Mean fetal breathing incidence decreased rapidly in the IUGR group and was significantly lower in the IUGR group during the final 15-minute period when compared with normal fetuses ($p < 0.05$). Mean fetal breathing rates were similar for both groups and were unchanged during and after hyperoxia (Fig. 2). Biophysical parameter alterations appeared to be unrelated to the transcutaneous oxygen levels achieved.

Baseline mean fetal body movement incidence was significantly lower in fetuses with IUGR when compared with the normal group ($p < 0.05$). After maternal hyperoxia, mean fetal body movement incidence increased significantly in the IUGR group ($p < 0.02$), achieving a maximal level at 30 minute after hyperoxia (Fig. 3). This alteration in the incidence of body movements was not observed in the normal group of fetuses.

Analysis of these data with receiver-operating characteristic plots yielded optimal discrimination points for both fetal breathing and body movement responses after maternal hyperoxia. Using an increase of more than 75% over mean baseline fetal breathing incidence and an increase of more than 250% over mean baseline fetal movement incidence, sensitivity was 56% (10 of 18); specificity, 94% (32 of 34); positive predictive value, 83% (10 of 12); and negative predictive value, 80% (32 of 40). Grouping the IUGR fetuses according to subtype (symmetric or asymmetric) did not improve these diagnostic values.

Comparison between the IUGR and nonIUGR groups on the basis of fetal weight showed that placental weight ratio also failed to show a difference. Assessment of amniotic fluid pockets did not show that fetuses in either group had maximal pocket dimensions of less than 2 cm by 2 cm.

Comment

The detection and antenatal evaluation of fetuses with IUGR continues to present a problem for obstetricians. Efforts at screening for IUGR, regardless of method, yield maximum sensitivities of only 60% to

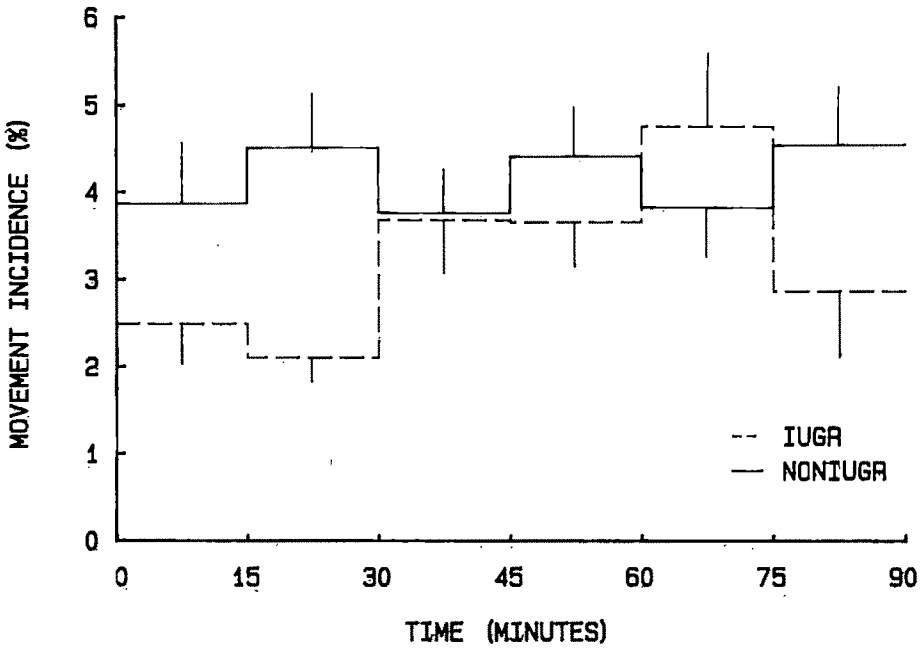

Fig. 3. Fetal body movements before, during, and after maternal hyperoxia (given at time = 30 minutes). Baseline fetal movement was significantly lower ($p < 0.05$) in IUGR group and increased significantly ($p < 0.02$) after hyperoxia period.

70% and specificities of approximately 90%.[7] Doppler flow velocimetry of umbilical artery blood flow provides improved sensitivity for the detection of IUGR.[8] However, this approach is associated with an increase in false-positive rates, thus requiring antenatal testing of many normal fetuses. The contraction stress test, regarded as a vigorous assessment of placental respiratory reserve, is usually reassuring in the presence of IUGR.[9] The nonstress test may also fail to reveal the elevated risk status of these fetuses.[10]

Biophysical testing, which provides the additional parameters of fetal breathing and movement, as well as amniotic fluid volume, has been shown to be beneficial in assessing the fetus with IUGR, particularly through its detection of oligohydramnios.[11] Investigations of fetal breathing activity in fetuses with IUGR have had conflictual results either because of small study populations or lack of standardized study conditions. Trudinger et al.[2] demonstrated that approximately 55% of fetuses with IUGR exhibited a decrease in fetal breathing activity after glucose loading, whereas the remainder showed an increase in fetal breathing. In a study of fetal breathing and behavioral states, van Vliet[12] et al. reported a decrease in breathing incidence in growth-retarded fetuses, whereas fetal movement was reported to be within or just below the expected norm. The maternal administration of oxygen as a potential diagnostic probe for placental respiratory function is based on previous observations of the biophysical effects of fetal hypoxia in chronic animal models. Bissonette[13] reported that fetal lambs exhibited more frequent apneic episodes when acute fetal hypoxia was induced. Martin et al.[14] reported similar data using rhesus monkeys. These effects probably resulted from an increase in high-voltage electrocortical activity and suppression of spinal reflexes. Clinical studies regarding the effects of maternal hyperoxia in pregnancy have demonstrated that fetal breathing movement and fetal movement are unaffected in normal third-trimester fetuses,[3, 5] whereas breathing movements may be increased in growth-retarded fetuses.[3, 13] The present study suggests that maternal hyperoxia is associated with significant increases in fetal breathing and body movement incidences in most fetuses with growth retardation. These changes in fetal activity do not occur uniformly and appear to be transient. The observed increases in these fetal activities, which follow maternal hyperoxia, are particularly dramatic when compared with those observed in normal fetuses. When IUGR results from chronic placental insufficiency, it is often associated with a redistribution of cardiac output to maintain substrate and oxygen supply to vital fetal systems, that is, brain, heart, and adrenal glands. It follows that reductions in fetal breathing and trunk movements may conserve energy and decrease oxygen requirements. Fetal responses to increased environmental oxygen may vary according to several preexisting conditions, such as the relative level of hypoxia and metabolic balance and the integrity of central regulatory mechanisms. Fetal biophysical responses to supplemental

oxygen may also be related to the severity of growth retardation, its duration, and its origin, since not all such cases result from placental respiratory insufficiency or are evident at the time of initial assessment.

Direct, noninvasive measurement of fetal oxygen levels is not presently possible; therefore interpretation of the results of this study are subject to certain limitations. Although the study sample is relatively small, the length of observation and the standardization of study conditions support the conclusion that these observed changes in biophysical activity were not likely to represent fetal state alterations. In addition, these findings are in general agreement with those previously reported by Ritchie and Lakhania[3] and Dornan and Ritchie.[15] Finally, fetal gestational ages were confined to the late third-trimester to avoid potential differences caused by maturational influences on control mechanisms of the central nervous system.

Our observation that maternal oxygen administration is associated with increased fetal breathing and body movement incidences in most fetuses with IUGR suggests that this maneuver may be a promising tool for intrauterine evaluation. A prospective clinical trial, using this approach on a larger randomized population sample, would be necessary to determine its applicability for obstetric management.

Fetal radius length: A critical evaluation of race as a factor in gestational age assessment

Lyndon M. Hill, MD, David Guzick, MD, PhD, Marion L. Thomas, RT, RDMS, and Joanne K. Fries, RDMS

Pittsburgh, Pennsylvania

Growth of the fetal radius was examined ultrasonographically in a prospective cross-sectional study of 290 white and 63 black patients between 12 and 43 weeks' gestation. The mean of radius length and 95% predictive intervals were calculated for each week. The most efficient description of the data was given by a simple log-linear model. The slopes for the white and black study groups estimated were distinctly different. Consequently, a single equation was estimated that considers race when assessing gestational age from radius length. (Am J Obstet Gynecol 1989;161:193-9.)

Key words: Fetal radius, gestational age assessment, ultrasonography, race

Queenan et al.[1] were among the first to suggest the use of long bone lengths to determine fetal age. They found the measurement of the femur to be the most readily reproducible. The radius and ulna were measured as a complex. Because the ulna extends further into the elbow than the radius, the inability to separate and measure the same long bone of the forearm would invariably lead to errors in gestational age assessment. Recently, two European studies[2, 3] reported their experience with radius length to assess gestational age.

The possible effect of race on fetal long bone length has not been properly assessed. Although a few studies[4, 5] failed to find a difference in femur length between blacks and whites, a complete evaluation extending throughout gestation has not yet been published.

The purpose of our investigation was twofold: to establish appropriate standards for fetal radius length and menstrual age in a white population within the United States, and to compare the results obtained with a similar formula devised for blacks.

Material and methods

The study group consisted of 290 white and 63 black women. Each patient had to meet the following pregnancy-dating criteria before admission into the study: regular menses, an accurate date of the last menstrual period, a positive pregnancy test by 7 weeks' gestation, and a pelvic examination by 8 weeks' gestation. Patients with diseases known to affect fetal growth (e.g., diabetes mellitus) were excluded. Patients with multiple gestations were also excluded. The gestational ages of the study population ranged from 12 to 43 weeks. All neonates were ≥10th percentile for weight at the time of delivery.[6]

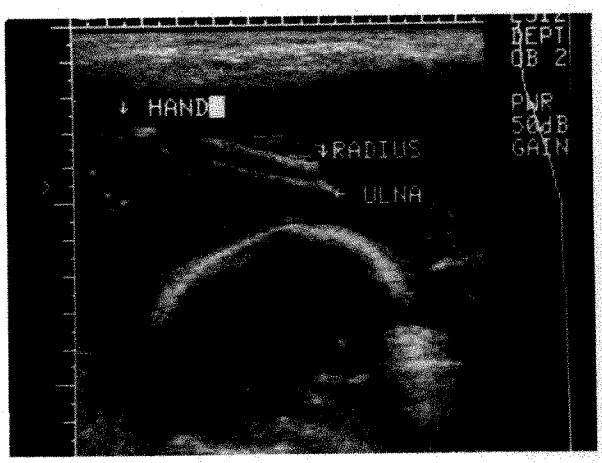

Fig. 1. Radius and ulna at 23 weeks' gestation.

The ultrasonographic measurements of the length of the fetal radius were made with a commercial linear array real-time system with a 3.5 MHz transducer at a focal zone of 5 to 12 cm. Both ends of the radius had to be identified distinctly from the ulna before an image was obtained (Fig. 1). We found the radius only slightly more difficult to image than the femur despite its greater range of motion. All measurements were taken with electronic calipers calibrated to the velocity of sound in tissue of 1540 m/sec.

Statistical analysis

Statistical analyses were conducted using the Minitab statistical software package on VAX 11/750 and DEC 20 computers. Data were evaluated in stages.

First, the means and SDs of radius length for each

gestational age were calculated. These results were then plotted to assess the nature of the relationship (linear, curvilinear) between gestational age and radius length.

Second, alternative regression equations (linear, quadratic, log-linear) relating gestational age to radius length were estimated. In comparing these equations, we sought the simplest expression in which all estimated coefficients were significantly different from zero and in which there was the highest coefficient of determination and lowest residual SD.

Third, the best regression equation was estimated separately for whites and blacks. Differences between the estimates for whites and blacks were then systematically evaluated.

Results

The relation between gestational age and radius length for the 290 white subjects is plotted in Fig. 2. Estimates of five alternative regression equations fit to these data are presented in Table I.

Fig. 1 shows that the relation between gestational age and radius length is slightly curvilinear. Although a linear model (equation 1, Table I) explains the data well ($R^2 = 0.945$), the squared term of a quadratic model (equation 2, Table I) appears with a significant coefficient and the R^2 value improves slightly. A cubic term (equation 3) was statistically significant, but at the expense of the linear term. Its inclusion did not improve the overall explanatory power of the model.

The most efficient description of the data was provided by a simple log-linear model (equation 4). This equation maximized R^2, using only one predictor variable that was highly significant. Moreover, an increase in variability seen on residual plots for equations 1, 2, and 3 (not shown) was not evident with equation 4 (Fig. 3). The addition of a quadratic term to equation 4 (i.e., equation 5) did not improve its fit.

Thus, for the 290 white subjects, the estimated regression equation was:

$$\text{Log}_e\,(\text{Gestational age}) = 2.424 + 0.226\,(\text{Radius length})$$

When a similar analysis was conducted for the 63 black subjects, the log-linear equation was also found to provide the best fit of the data, but the coefficient estimates were somewhat different:

$$\text{Log}_e\,(\text{Gestational age}) = 2.427 + 0.219\,(\text{Radius length})$$

Four models were developed to compare the regression equations for white and black subjects:

Model I: General. The slope and the intercept for the two equations are different.

Model II: Parallel regression. In this model for $\log_e$ gestational age, the slope parameters for radius for the two populations are the same, but the intercepts are different.

Table I. Estimated regression equations for white subjects ($N = 290$)

Equation No.	*Dependent variable**	*Coefficients for independent variables†*				
		Constant	*Radius*	*Radius²*	*Radius³*	R^2
1	Age	6.16 (21.13)	5.61 (70.54)			0.945
2	Age	11.13 (15.95)	2.29 (5.26)	0.49 (7.71)		0.954
3	Age	15.23 8.72	−1.92 (−1.13)	1.79 3.48	−0.12 (−2.56)	0.955
4	Log_e(age)	2.42 247.48	0.23 (84.78)			0.961
5	Log_e(age)	2.39	0.25	−0.004		0.961

*Age is gestational age in weeks.
†t Statistics for corresponding estimated coefficients are shown in parentheses.

Table II. Summary of models that compare black and white subjects*

Variable	*Model I*	*Model II*	*Model III*	*Model IV*
Intercept, all subjects	—	—	2.424 (282.17)	2.425 (278.86)
Radius, all subjects	—	0.224 (95.88)	—	0.224 (94.88)
Intercept, whites	2.427 (126.68)	2.408 (229.14)	—	—
Intercept, blacks	2.424 (251.69)	2.429 (279.25)	—	—
Radius, whites	0.219 (42.50)	—	0.219 (78.44)	—
Radius, blacks	0.226 (86.02)	—	0.226 (95.12)	—
Error [SD]	0.052	0.052	0.052	0.053
Residual sum of squares	0.956	0.960	0.956	0.983
Degrees of freedom	349	350	350	351

**t* Statistics for the corresponding estimated coefficient are shown in parentheses.

Model III: Concurrent regression. In this model, the intercepts are equal, but the slopes are different (Fig. 4).

Model IV: Coincident regression. The regression equations for the two populations are the same. This suggests that the same equation may be used to define the study groups.

Table II summarizes the estimate for the four alternative models. The plausibility of models II, III, and IV were tested against the general model (model I) by using the F test. For our data, the F statistics were as follows:

Model II versus model I: $F = 1.46$ ($p > 0.10$)
Model III versus model I: $F = 0.09$ ($p > 0.10$)
Model IV versus model I: $F = 4.95$ ($0.005 < p < 0.01$)

From these analyses, we concluded that models II and III were as good as the least restrictive model, model I (i.e., the F statistics were not statistically significant). Because model I was statistically different from model IV (coincident regression model), the latter cannot be utilized to explain the relationship between radius length and gestational age for both populations. Models II and III were then compared with model IV:

Model IV versus model II: $F = 8.43$ ($0.001 < p < 0.005$)
Model IV versus model III: $F = 9.83$ ($0.001 < p < 0.005$)

Thus models II and III were better than model IV. Because model III not only had a larger F statistic, but also a smaller error of variance (Table I), we chose model III as the best single equation for the prediction

Table III. Gestational age and 95% prediction intervals for radius length in a white population (values for blacks in parentheses)

of gestational age from radius length for both populations:

$$\text{Log}_e\,(\text{Gestational age}) = 2.424 + 0.220\,(\text{Radius: black}) + 0.226\,(\text{Radius: white})$$

In the above equation, a zero should be used for "radius: white" when a black patient is evaluated, and vice versa. Radius length is measured in centimeters.

In model III there is concurrence of the two populations at a radius length equal to zero, which corresponds to a gestational age of 11 weeks. Before 11 weeks' gestation, the radius cannot be reliably identified and measured. The coefficient of determination for model III is 96.3%.

The lower and upper limits of the 95% prediction intervals for gestational age when radius length and

Table IV. Mean and SD of the residuals for each technician (subset of 290 white patients)

Technician	*No. of Measurements*	*Mean*	*SD*
1	22	0.28	1.45
2	67	-0.16	0.97
3	68	0.15	1.00
4	24	-0.29	0.50
5	63	-0.05	0.87
6	10	0.10	1.14
7	36	0.19	1.12

maternal race are known (values for blacks are given in parentheses) are listed in Table III.

To test for the existence of technician effect, standardized residuals from the fitted line (model IV) for the subset of 290 white patients were used. Table IV shows the number of measurements taken by each technician, the mean, and SD of the residuals. One-way analysis of variance yielded an F ratio of 1.14, which is not significant. Hence the interobserver effect on the measurements obtained was insignificant. The intraobserver difference for measuring 27 radial lengths twice a day was almost always within a range of ± 1 mm.

Comment

Several investigators have derived gestational age from long bone length.[1-3, 7-10] Initially, attention was focused on the fetal femur. Its size, absence of interfering anatomic structures, and the inherently smaller range of motion of the proximal as opposed to the distal long bones allow the femur to be measured quite easily. With improvement in the resolution of real-time equipment, finer fetal anatomic detail can now be appreciated. Hence the radius and ulna may be differentiated, whereas in the past they were measured as a "complex."[1]

Since our study began, three groups[2, 3, 11] have reported their results of gestational age assessment by radius length. Table V compares the results from these three studies and our investigation; the majority of radius lengths are within a 2-mm range.

In 1984, Jeanty et al.[7] published their results with respect to the humerus, ulna, and tibia. A linear quadratic regression was used to predict gestational age. In Table VI, the results of their study are compared with our investigation. It can be seen that the use of radius length as a predictor of fetal age leads to a better fit, even for the linear quadratic model. The variability for gestational age determination from the femur length and radius length (Table VII) is identical.

Several studies that evaluated femur length,[3, 8-10] and our assessment of radius length, concluded that variance increases with the size of the long bone measure-

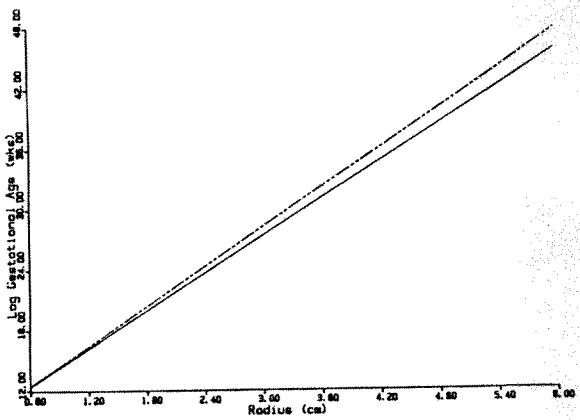

Fig. 4. The concurrent regression model has different slopes but the same intercept.

ment. However, Jeanty et al.[7] claimed that the error variance of the linear quadratic model did not increase with increasing lengths of the long bone. This conclusion was based on their use of the Bartlett test to assess significance. As emphasized by Warda et al.,[10] this was not the best test to use for their purpose because of an inadequate sample size at each week of gestation (approximately 23 measurements per week). Hence the results obtained by Jeanty et al.[7] may not have been reliable. Our results concur with the findings of Warda et al.[10] with respect to femur length; i.e., $\log_e$ transformation of gestational age should be used to reduce the systematic variability discovered on the residual plot.

Although several technicians were involved in the accumulation of the data, there were no significant interobserver differences in the results. This indicates that the landmarks for delineating the ends of the radius were readily reproducible between observers.

Scammon and Calkins[12] established the classic anthropometric interrelationships and the relationship between anthropometric variables and gestational age. Specifically, with respect to fetal skeletal maturity, Garn et al.[13] and others have shown that the female fetus reaches a given stage of development at an earlier age than the male. Black infants tend to be shorter than white infants of the same gestational age. Miller and Merritt[14] found that crown-heel lengths are affected not only by race, gestational age, and fetal sex but also by maternal height and, to a slight degree, parity. The differences noted in our investigation are merely an extension of the neonatal data accrued by others.[14]

Sabbagha et al.[15] compared the difference between the biparietal diameters from 107 white and 91 black normal pregnant women. Only minor differences (up to 2 mm after 30 weeks' gestation) were noted. When the length of the femur was assessed in racially dissimilar populations, a slight difference was found.[16] How-

36-42.0	3.9-4.4	3.8-4.3

ever, the latter study only compared fetuses up to a gestational age of 24 weeks. Similarly, Ruvolo et al.[4] could not find any differences in gestational age assessment by femur length in 61 black and 102 white patients between 19 and 32 weeks' gestation. For purposes of comparison, it is important to note that the authors did not extend their study to term. Moreover, they did not derive specific gestational age formulas for their black and white patients and then evaluate the results. They chose to compare their femur length data with a previously published chart.[9] Evaluation of their composite assessment of gestational age in a black population by Hadlock et al.[5] suffers from the same design flaw. This type of comparison may obscure small differences between populations because groups are compared with a standard instead of with each other. After deriving regression equations for each subpopulation, we noted a statistically significant difference in gestational age prediction by radius length for whites and blacks—a 10-day difference in gestational age assessment was noted in the third trimester. Although this difference lies below the estimated variability of radius length for any gestational age, we feel that this difference is significant enough to warrant the incorporation of race into the assessment of gestational age utilizing radius length.

Pregnancy after aortofemoral bypass grafting in a diabetic patient

P. J. Bradley-Watson, FRCS, FRCOG
Dyfed, Wales

A case of pregnancy after an aortofemoral bypass graft for atherosclerosis in an insulin-dependent diabetic is described. Pregnancy after this type of surgery in a diabetic patient has not been described previously. (AM J OBSTET GYNECOL 1989;161:200-1.)

Key words: Pregnancy, diabetes, aortofemoral bypass graft

Although pregnancy after an aortofemoral bypass has been described previously,[1] I could not find any reports of pregnancy with the added complication of insulin-dependent diabetes.

Case history

The patient was 32 years old and had been an insulin-dependent diabetic since the age of 9 years. At the age of 20, the patient had her first pregnancy, which was complicated by premature normal delivery of a healthy 2155 gm normal infant at 35 weeks' gestation. At the age of 30, the patient was seen with intermittent claudication in both legs, but particularly of the left calf. She smoked 10 cigarettes a day and there was a family history of arterial disease. There were also symptoms of peripheral paresthesia, and absent pulses at the femoral level and below in both lower limbs.

An aortogram showed a complete block of the aorta just below the level of the renal arteries. The lower aorta was very narrow and iliac vessels had thick walls and heavy calcification. An aortoendarterectomy and end-to-end aortobifemoral bypass graft with a knitted Dacron graft were done. Because of the extension of the disease, a left renal endarterectomy was also performed. Histologic study of the specimen confirmed atheroma. The patient made a good postoperative recovery and a scan of the abdomen revealed that the graft was functioning well. The symptoms greatly improved with relief of claudication. The femoral pulses were good but there were no pulses distal to this.

In 1988 she was seen in the tenth week of her second pregnancy; dates were confirmed by sonography. She had not had preconceptual advice. The patient was adamant that she wanted to continue the pregnancy.

Throughout the pregnancy her diabetes was monitored at the joint obstetric-medical clinic with the diabetic specialty nurse in attendance. Blood glucose levels were monitored on a home basis with a glucometer; the insulin dosage (a combination of Actrapid and Monotard twice daily) was modified accordingly. A capillary blood glucose series was done in the home on a twice-weekly basis to check the accuracy of the glucometer. Regular fructosamine levels were studied on all occasions and were within normal levels; however, the level at the inital visit was raised (2.38 nmol/L). The retinas were examined during the pregnancy and there were no adverse changes. The renal function tests were done at the initial visit and were within normal limits. The aorta and iliac vessels were examined by ultrasonography at the initial visit and throughout the pregnancy and did not alter throughout the pregnancy. The diameter of the aorta was 18 mm and the iliac vessels measured 8 mm in diameter.

The pregnancy was monitored with the usual clinical parameters. The fetal well-being was monitored both clinically and by serial ultrasonography. There was no evidence of intrauterine growth retardation or diabetic macrosomia, either clinically or on ultrasonographic scans. From the thirty-fourth week of pregnancy a fetal kick chart was kept and was always satisfactory. The patient was admitted to the antenatal ward on only one occasion, at 33 weeks, because of possible decrease in fetal movements, but all fetal investigations carried out at that time were satisfactory.

The patient was admitted at 38 weeks for a planned induction of labor because of diabetes. An ultrasonographic estimation of fetal weight carried out at this time was 3.64 kg. Labor was induced with amniotomy and intravenous Syntocinon. The first stage of labor lasted 3 hours 35 minutes, and the second stage 30 minutes with normal delivery of a healthy infant weighing 3.4 kg. During labor the patient's diabetes was controlled with an insulin and dextrose infusion with regular blood glucose estimations. The infant was observed in the special care baby unit for 48 hours and only needed early feeding to maintain adequate blood glucose levels. The patient's puerperium was uneventful, and throughout the pregnancy and puerperium there

were no detrimental symptoms or signs concerning the blood supply to the lower limbs and pelvis.

Comment

This is an unusual case of a diabetic patient with the added complication of an aortofemoral bypass. A pregnancy has been described after aortofemoral bypass, but not in a woman with diabetes.[1] The blood supply to the pelvic organs did not appear to have been compromised enough to cause any degree of intrauterine growth retardation, as seen in the previously reported case. Weir and Willocks[2] reported a case of a pregnancy after a right aortofemoral graft for thrombosis associated with intrauterine growth retardation, but that case was also complicated by malignant phase hypertension.

The problem of possible prophylactic anticoagulant therapy throughout the pregnancy was discussed at the initial antenatal visit. It was decided that no anticoagulants would be used prophylactically because the patient had already had a good response after surgery with no complications. In reviewing the literature concerning pregnancy after aortofemoral grafts, half of the patients had anticoagulant therapy. We decided that no prophylactic anticoagulants would be used because of the added complication of diabetes. Pregnancies have been previously reported after coronary artery bypass grafting,[3] and in this situation prophylactic anticoagulants were not used. In conclusion, this case demonstrates an uncomplicated outcome of a pregnancy complicated by two difficult medical problems in which the obstetrician may have advised differently at the commencement of the pregnancy.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular Journal subscription.

Fentanyl citrate analgesia during labor

William Rayburn, MD, Anne Rathke, RN, M. Patricia Leuschen, PhD, Jan Chleborad, MD, and William Weidner, MD

Omaha, Nebraska

Fentanyl citrate is a potent short-acting narcotic reported to cause less nausea and sedation than morphine or meperidine hydrochloride. The purpose of this prospective investigation was to determine whether a safe but adequate intrapartum dosing schedule is possible. A total of 137 women with uncomplicated term pregnancies were offered a standard intravenous dose (50 mcg or 100 mcg hourly as needed) of fentanyl citrate during active labor. Temporary analgesia and mild sedation were apparent in each case. The cumulative dose varied in accordance with maternal needs (mean, 140 ± 42 μg; range, 50 mcg to 600 μg). Apart from a brief decrease in fetal heart rate variability that lasted 30 minutes, no worrisome pattern was apparent from exposure to fentanyl citrate. Pediatric examinations were performed without knowledge of analgesic therapy on infants exposed to fentanyl citrate and those not exposed to analgesics. No differences were found in frequencies of newborn depressed respirations, low Apgar scores, or neurologic and adaptive capabilities at two hours and 24 hours postnatally. With the use of the described dosing schedule, fentanyl citrate was helpful during labor and did not cause immediate or prolonged hazards to the mother and unborn infant. (Am J Obstet Gynecol 1989;161:202-6.)

Key words: Fentanyl citrate, labor, narcotics

Fentanyl citrate is a synthetic opioid used primarily during the anesthetic period for premedication, induction and maintenance, and postoperative analgesia. Compared with meperidine hydrochloride and morphine in nonpregnant adults, fentanyl citrate has a greater analgesic potency, shorter duration of action (30 to 60 minutes), and lower risk for nausea and respiratory depression.[1] Its analgesic and euphoric effects are equally antagonized by opioid antagonists, and no active metabolite is present.

Experience with intravenous fentanyl citrate during pregnancy has been limited. The manufacturer (Sublimaze, Janssen, N.J.) has written in the package insert that there are insufficient data to support its use during labor and delivery. Because of the drug's potential advantages over more traditional narcotics, we attempted to determine how much fentanyl citrate is requested during labor and whether the newborn infant is affected.

Material and methods

Data were gathered between January 1988 and April 1988 after permission was granted by our Institutional Review Board. Women in labor ≥37 weeks' gestation with no active medical or obstetric complications were eligible for enrollment. Each study participant was offered intravenous fentanyl citrate if epidural anesthesia was not desired. Those who requested fentanyl citrate were informed of its potential side effects (nausea, sedation, hypotension, and respiratory depression).

A standard 50 μg or 100 μg dose was administered intravenously as often as every hour on request during active labor (cervical dilation 3 to 10 cm). This dose range was known to be equianalgesic to 5 to 10 mg of morphine or 37.5 to 75 mg of meperidine hydrochloride.[1] The lower 50 μg dose was usually given initially unless the patient was perceived by the physician or nurse to be in severe pain. The number of requests for the drug and the total dose required during labor were recorded. A 0.02 mg (1 ml) dose of the neonatal preparation of naloxone hydrochloride (Narcan, DuPont, Wilmington, Del.) was available for intramuscular administration in the event of initial neonatal respiratory difficulties presumably from narcotic excess.

Blood was drawn from the maternal antecubital vein and umbilical vein at delivery for serum fentanyl citrate determinations. Each sample was centrifuged at 8000 *g* for 10 minutes. A 1 to 5 ml plasma specimen was drawn and stored at −20° C until the time of assay. All plasma samples were assayed simultaneously and in duplicates in accordance with the radioimmunoassay technique (Janssen Pharmaceutics, Piscataway, N.J.) described by Michiels et al.[2] The antibody used in this technique was described as being highly sensitive and specific for fentanyl citrate with no significant cross-reactivity with fentanyl citrate metabolites or close analogs.

Newborn findings were compared with a similar group of consecutively chosen term infants born during

included Apgar score determinations at 1 and 5 minutes and selective umbilical blood gas measurements (pH, base excess) if respiratory depression of the fetus or a worrisome type of fetal heart pattern was present.

Each infant underwent complete neurologic and adaptive capacity scoring at 2 to 4 hours and 24 hours postnatally. The scoring system described by Amiel-Tison et al.[3] was used because it is less time-consuming (average, 4 minutes per examination) with presumably less interobserver bias than Scanlon scoring. The newborn evaluation included assessments of passive and active tone, primary reflexes (automatic walking, Moro reflex, and sucking), responses and habituation to sound and light stimuli, alertness, and consolability. Examinations were performed by a pediatrician (J. C.) or qualified pediatric nurse (A. R.) without knowledge of previous intrapartum drug exposure.

Averaged data were reported as means ± 1 SD value. Statistical comparisons were made with the Student *t* test and χ^2 test. A *p* value <0.05 was considered to be statistically significant.

Table III. Mean adaptive capacity and neurologic scores between infants exposed or not exposed in utero to fentanyl citrate*

	Total fentanyl citrate dose				
	50 μg (n = 32)	*100 μg (n = 55)*	*150 to 200 μg (n = 23)*	*≥200 μg (n = 27)*	*None (n = 112)*

*None of the scores for infants exposed to fentanyl citrate was different from those of the infants who received none.

Results

A total of 137 participants were prescribed fentanyl citrate during the 4-month study period. This represented 55% (137:249) of the women who underwent labor at term without previous complications. Table I compares the profiles between the study and control pregnancies. The women who received fentanyl citrate were more likely to be younger and nulliparous. They also were more likely to require oxytocin and to have longer labors after hospital admission.

Fentanyl citrate was requested 308 times. The average number of requests per case was 2.3 ± 0.8 (range, 1 to 7 doses). The number of injections per case is shown in Fig. 1. Approximately two thirds (67.9%, 93:137) required two or fewer doses. Fig. 1 also displays the total dose administered per case. The cumulative dose ranged widely (50 μg to 600 μg) according to individual patient needs, but the mean was 140 ± 42 μg. Approximately two thirds (63.5%, 87:137) received ≤100 μg, whereas 90.3% (110:137) received <300 μg.

Questioning of participants by nursing staff revealed the onset of analgesic activity to be within 5 minutes and it usually lasted approximately 45 minutes. Fentanyl citrate did not completely eradicate uterine contraction pain, especially when pain was severe in the late phase of labor, but it did "take away the edge." Mood modification, temporary relief of fears, and relaxation were present in all cases. Depressed maternal respirations (<12 respirations per minute) were not seen. If the parturient was tired, drowsiness often occurred between contractions. Transient nausea was present in 13 cases (9.5%), but never so much as to require antinauseant medication. Such episodes usually occurred in the late phase of labor.

Serum concentrations of fentanyl citrate at delivery are compared between the mother and the fetus (umbilical cord) in Fig. 2. The concentrations of fentanyl citrate were significantly less ($p < 0.03$) for the cord sera than maternal sera, regardless of the fentanyl citrate dose. There was a significant linear relationship between the fentanyl citrate dose and cord levels ($p < 0.05$). In contrast, there was not a linear relationship between fentanyl citrate dose and maternal levels. This may be explained by the longer time from last dose until delivery between the >200 μg cumulative dose and the 100 to 200 μg dose groups (82.3 ± 47.2 minutes versus 97.7 ± 53.6 minutes).

Most infants exposed to fentanyl citrate in utero did well immediately after delivery with routine observation (Table II). The frequencies were low for depressed respirations by 90 seconds after delivery, and Apgar scores <7 were no more common than those for the control group. None of the study infants had an umbilical blood pH <7.25 or base excess < −6.0. Narcan was required in one case in which a single 50 μg dose of fentanyl citrate had been prescribed to the mother. The presence of three loops of cord wrapped around the infant's neck likely contributed to the depressed respirations. Despite the fentanyl citrate and cord entanglement, the 1- and 5-minute Apgar scores were 6 and 8, respectively, and the infant's depressed respirations improved.

Infants exposed to fentanyl citrate had respiratory rates equal to those in the control group during the first 2 to 4 hours (Table II). Apneic spells were not evident. Mean blood pressures recorded from the right arm and mean heart rates were not significantly lower than the control group.

Findings on neuroadaptive examinations compared favorably between infants in the study and control groups (Table III). Adaptive and neurologic scores determined at approximately 2 and 24 hours postnatally were reassuring, similar to the control groups, and dose dependent. A total score <30 was no more common ($p < 0.05$) if the total fentanyl citrate dose was >200 μg at 2 hours than for a lesser dose (5:38, 13.2% versus 6:99, 6.1%) and 24 hours (2:38, 5.3% versus 1:99,

1.0%). The last dose was usually given 2 hours before delivery (mean 112 ± 29 minutes; range, 27 to 183 minutes) and did not appear to influence the unlikely finding of depressed neonatal respirations or delayed neuroadaptive adjustments at the examination after 2 hours.

Comment

This study was undertaken to assess the usefulness of fentanyl citrate during labor because of its known rapid and short-acting analgesic effects with less anticipated depression in nonpregnant persons.[1] With the use of the chronic maternal-fetal sheep preparation, Craft et al.[4, 5] reported that fentanyl citrate administered intravenously or epidurally in standard doses crossed the placenta easily without adverse effects to the mother or fetus. No significant deleterious changes were found in uterine blood flow, uterine tone, and maternal or fetal cardiovascular and acid-base parameters. Results from this prospective investigation indicated that fentanyl citrate used intermittently during active labor is well tolerated by the participants. The more prolonged labors in the study group would be attributed more to the hospital admissions being in the earlier phase of labor and to the differences in pregnancy profiles (primigravida, unprepared childbirth, and need for oxytocin administration) than to the effects of the drug.

A preliminary report in humans by Eisele et al.[6] revealed that neonates were not impaired when the drug was given to the mother within 10 minutes before delivery during an elective cesarean section. The few neonates who required supplemental oxygen or naloxone in our experience often had accompanying complications such as meconium passage in utero or cord entanglements. This need for oxygen was less common than that of the control group.

Food and Drug Administration guidelines recommend neurobehavioral studies for any drugs used during labor. Findings in this study also provide reassurance that the drug was not associated with any increased risk of impaired neurologic or adaptive adjustments during the first 24 hours postnatally. This was true even when relatively higher total doses (>200 μg) were administered to the participants, although the number of study cases is not large. Infants exposed to fentanyl citrate were not more likely to have diminished passive or active muscle tone or impaired responses to light or sound stimuli.

With the use of the described dosing regimen in this investigation, an accumulation of fentanyl citrate was not considered to be harmful. Serum concentrations of fentanyl citrate remained consistently less in umbilical cord than in maternal circulation at delivery, regardless of the dose. More confidence with frequent intravenous dosing and less prolonged effects were positive findings with this narcotic. Despite these reassurances, the respiratory depressant effect of fentanyl citrate may be more prolonged than the analgesic effect, necessitating close observation of the parturient. We consider our observations to be encouraging and suggest a need for further intrapartum studies to compare fentanyl citrate with more conventionally used narcotics.

Significance of D-mannose as a sperm receptor site on the zona pellucida in human fertilization

Kazumasa Mori, MD, Toshifumi Daitoh, MD, DMSc, Minoru Irahara, MD, DMSc, Masaharu Kamada, MD, DMSc, and Toshihiro Aono, MD, DMSc

Tokushima, Japan

The role of monosaccharides in human fertilization was studied by testing their effects on penetration of spermatozoa into mature human oocytes (zona penetration test). When oocytes were pretreated with concanavalin A, wheat germ agglutinin, or *Ricinus communis* agglutinin-I at a concentration of 100 μg/ml, no spermatozoa were found to bind to or penetrate through the zona pellucida. Penetration of spermatozoa was restored when the zona pellucida pretreated with wheat germ agglutinin and *Ricinus communis* agglutinin-I were rinsed with *N*-acetyl-D-glucosamine (wheat germ agglutinin inhibitor) and D-galactose (*Ricinus communis* agglutinin inhibitor), respectively. Conversely, the blocking effect of concanavalin A on sperm penetration was not reversed by treatment with D-mannose (concanavalin A inhibitor). Furthermore, pretreatment of spermatozoa with D-mannose (50 mmol/L) completely inhibited sperm penetration through the zona pellucida. However, sperm penetration was clearly demonstrated when the zona pellucida was pretreated with D-mannose. These data suggest that D-mannose residues are essential in, or sterically closely related to, the sperm receptor site on the human zona pellucida. (AM J OBSTET GYNECOL 1989;161:207-11.)

Key words: Sperm-ovum interactions, carbohydrates, D-mannose, human zona pellucida, spermatozoa receptor

As a first step in fertilization, spermatozoa bind to and penetrate through the zona pellucida that surrounds mammalian eggs. The zona pellucida is thought to have a receptor site for species-specific binding of spermatozoa. We previously demonstrated that monoclonal antibodies against common antigens of human and porcine zona pellucida and alloantibodies to human spermatozoa inhibited fertilization of human eggs in vitro. These data suggest that antigens on both gametes are essential in human sperm-egg interaction.[1,2] As shown by many investigators in a wide variety of species,[3-12] including mammals, carbohydrate determinants on the zona pellucida are involved in sperm-egg interaction. However, there have been no detailed studies on the role of carbohydrate determinants on the zona pellucida in fertilization of human eggs because of the limited availability of human oocytes. Our preliminary experiments with fluorescein-conjugated lectins demonstrated the presence of monosaccharide chains with terminal D-mannose, D-galactose, and *N*-acetyl-D-glucosamine, but not L-fucose residues in the human zona pellucida. In this study, we investigated the role of monosaccharide chains in the human zona pellucida in gamete recognition.

Material and methods

Reagents. Concanavalin A (Con A), soybean agglutinin (SBA), wheat germ agglutinin (WGA), peanut agglutinin (PNA), *Dolichos biflorus* agglutinin (DBA), *Ricinus communis* agglutinin-I (RCA-I), and *Ulex europaeus* agglutinin-I (UEA-I) were purchased from Vector Laboratories, Inc. (Burlingame, Calif.). *Limulus polyphemus* agglutinin (LPA) was from Polysciences, Inc. (Warrington, Penn.). *N*-acetyl-D-glucosamine, D-galactose, D-mannose, and L-fucose were from E-Y Laboratories, Inc. (San Mateo, Calif.).

Collection of oocytes. Follicular oocytes were recovered from ovaries of patients who underwent laparotomy for gynecologic disorders. The oocytes were cultured as described previously.[1] They were allowed to mature for 48 hours at 37° C in Whittingham's T6 medium[13] containing 10% normal human serum under 5% carbon dioxide in air. Mature oocytes showing a first polar body were then stored in highly concentrated salt solution[14] (0.5 mol/L ammonium sulfate, 1.0 mol/L magnesium chloride, and 0.1% dextran) at 4° C and used for zona penetration tests within 3 months.

Zona penetration test. Before use, pooled oocytes were desalted in Dulbecco's phosphate-buffered saline solution overnight at 4° C. For insemination, freshly ejaculated spermatozoa from healthy men with consis-

Table I. Effects of exposure of human oocytes to various lectins on sperm binding to and penetration through the zona pellucida in vitro

UEA-I	13	8				

The zona pellucida was treated with the indicated lectin (100 μg/ml) for 1 hour at room temperature. When oocytes were exposed to Con A, WGA, and RCA-I, washed, and incubated in vitro with motile spermatozoa, spermatozoa were unable to bind to and penetrate through the zona pellucida. Experiments were repeated three times.

Table II. Effects of treatments of the zona pellucida with lectins and their inhibitory sugars

RCA-I	5	10	9	0	13	2

The zona pellucida was pretreated with Con A, WGA, or RCA-I and then incubated for 1 hour in Whittingham's T6 medium containing 0.1 mol/L specific inhibitory sugars for each lectin (D-mannose, *N*-acetyl-D-glucosamine, and D-galactose, respectively). The blocking effect of Con A on sperm penetration was not reversed by treatment with D-mannose, whereas penetration of spermatozoa was restored when the zona pellucida pretreated with WGA and RCA-I were rinsed with *N*-acetyl-D-glucosamine and D-galactose, respectively. Experiments were repeated three times.

*The oocytes subjected to this experiment were shown to be incapable of sperm binding and penetration when exposed to Con A, WGA, or RCA-I in experiment 1 of Table I.

†Oocyte was incubated in T6 medium only.

tently high semen quality were washed three times with T6 medium by centrifugation at 200 *g* for 5 minutes. T6 medium containing 10% normal human serum was then layered onto the highly concentrated sperm suspension and the preparation was incubated for 1 hour at 37° C under 5% carbon dioxide in air. The motile sperm swimming up into the upper T6 medium were collected and resuspended in T6 medium containing 10% normal human serum at a concentration of 1.0×10^6/ml. One oocyte was placed in 0.3 ml of the suspension covered with warm paraffin oil in a plastic culture dish (35 × 11 mm; Nunc, Roskilde, Denmark) and incubated for 6 hours at 37° C under 5% carbon dioxide in air. Then the oocyte was washed by pipetting and was examined with a phase-contrast microscope (Olympus, IMT, Tokyo) for sperm binding to and penetration through the zona pellucida.[1, 2] In this study, a single semen donor was used for one experiment. We could use only one oocyte for each regimen because it was impossible to prepare certain numbers of oocytes in one experiment because of the shortage of human oocytes available. Therefore we repeated the experiments to confirm the data.

First, the effects of lectins at concentrations of 100 μg/ml in Dulbecco's phosphate-buffered saline solution were examined. Oocytes were treated with 0.2 ml of various lectins (Con A, SBA, WGA, PNA, DBA, RCA-I, UEA-I, and LPA) for 1 hour at room temperature, were rinsed three times in T6 medium, and then were subjected to the zona penetration test.

For determination of the reversibility of the effects of the lectins, after treatment with the lectins the oocytes were rinsed for 1 hour in T6 medium containing 0.1 mol/L concentrations of specific inhibitory sugars for each lectin and were then subjected to the zona penetration test. In the first experiment, we tested the oocytes that had been incapable of sperm binding and penetration in the above study.

Second, the effects of sugars (*N*-acetyl-D-glucosamine, D-galactose, D-mannose and L-fucose)

Table III. Effects of treatments of spermatozoa with sugars

	Experiment 1		*Experiment 2*		*Experiment 3*		*Experiment 4*

N-acetyl-D glucos-amine	10	6						
D-galactose	9	4						
L-fucose	13	6	19	11	13	4		

Spermatozoa were incubated with 50 mmol/L concentrations of the indicated sugars for 30 minutes before the zona penetration test. Pretreatment with 50 mmol/L D-mannose completely inhibited penetration of spermatozoa through the zona pellucida, but pretreatment with *N*-acetyl-D-glucosamine, D-galactose, or L-fucose had no effect on their penetration. Experiments were repeated four times.

Table IV. Effects of treatments of the zona pellucida with D-mannose

Control	8	3	14	4	17	4	13	8
D-mannose	23	8	30	5	10	1	14	8

The zona pellucida was incubated with or without 0.1 mol/L D-mannose for 30 minutes at room temperature before the zona penetration test. Pretreatment of the zona pellucida with D-mannose did not block penetration of untreated spermatozoa. Experiments were repeated four times.

were examined by the zona penetration test. Motile spermatozoa collecting by the swimming up method at a concentration of 1.0×10^6/ml were incubated in T6 medium (0.3 ml) containing 50 mmol/L sugar for 30 minutes at 37° C under 5% carbon dioxide in air (osmolality of sugar mixtures, 326 to 338 mOsm). Then an oocyte was incubated in an aliquot of the suspension for 6 hours. In the case of D-mannose, zona penetration tests were also performed after spermatozoa and eggs had been treated separately with the sugar to study its effect on each gamete. In this study only concentrations of lectin and sugar of 100 μg/ml and 50 mmol/L, respectively, were used because of the limited availability of mature oocytes.

Results

Effects of lectins. Table I summarizes results in the zona penetration test with zona pellucida treated with various lectins. When oocytes were exposed to Con A, RCA-I, and WGA, washed, and incubated in vitro with motile spermatozoa, spermatozoa were unable to bind to and penetrate through the zona pellucida, although many came in contact with its surface. No blocking of sperm penetration was observed with untreated oocyte or oocytes treated with five other lectins (DBA, LPA, PNA, SBA, and UEA-I). In a second zona penetration test, the zona pellucida were rinsed with the inhibitory sugars of the respective lectins. Penetration of spermatozoa was restored when the zona pellucida pretreated with RCA-I and WGA were rinsed with D-galactose and *N*-acetyl-D-glucosamine, respectively. Conversely, the blocking effect of Con A on sperm penetration was not reversed by treatment with D-mannose, although the spermatozoa bound to the zona pellucida (Table II).

Effects of sugars. Table III summarizes results in the zona penetration test using spermatozoa treated with various sugars. Pretreatment with 50 mmol/L D-mannose completely inhibited penetration of spermatozoa through the zona pellucida, but pretreatment with *N*-acetyl-D-glucosamine, D-galactose, or L-fucose had no effect on their penetration. Although many spermatozoa pretreated with D-mannose came in contact with the zona surface, they did not penetrate through the zona pellucida. Furthermore, pretreatment of the spermatozoa with D-mannose blocked sperm penetration through the untreated zona pellucida, but pretreatment of the zona pellucida with D-mannose for 30 minutes did not block penetration of untreated spermatozoa (Table IV).

Comment

In this study, the zona penetration test was used to determine whether monosaccharides are involved in

human sperm-egg interaction. We used oocytes matured in vitro and stored in highly concentrated salt solution because storage under these conditions has been shown to preserve the bioactivity of the zona pellucida of oocytes.[14] The zona penetration test facilitates studies on the mechanism of human fertilization. Such studies are difficult because large numbers of mature oocytes are not available.

There are many reports on the blocking effects of various lectins on fertilization in a wide variety of species. Results have shown that Con A, RCA-I, and fucose-binding protein have blocking effects in brown algae,[3, 4] Con A, and fucose-binding protein in ascidians,[5] asparagus pea lectin (specific for L-fucose) in *Limulus polyphemus*,[6] and Con A, WGA, RCA-I, and DBA in the hamster.[7, 8] In our study spermatozoa failed to bind to and penetrate through human zona pellucida that had been pretreated with any of the lectins capable of binding to it (Con A, WGA, and RCA-I; preliminary data).

Four possible mechanisms for the blocking effects of lectins may be considered. (1) The lectin-binding sites may be essential components of the sperm receptor sites. Lectins may block fertilization by causing selective masking or conformational change of the sperm receptors. (2) The lectins may bind to other receptors in the vicinity of the sperm receptors, causing steric inhibition of sperm binding. (3) The lectins may bind to nonspecific membrane receptors, causing modulation of the membrane structure, including biochemical alterations in the nature of the zona pellucida to be resistant to proteinase dissolution,[7] which in turn causes nonspecific inhibition of fertilization. (4) The lectins bound to the zona pellucida may also bind to spermatozoa and thus prevent their penetration through the zona pellucida, because the surface of human spermatozoa and the zona pellucida share binding sites for Con A, WGA, and RCA-I (unpublished data). However, the mechanism of the blocking effect of Con A appears to be different from that of WGA or RCA-I, because the effect of Con A was not reversed by washing Con A–treated zona pellucida with D-mannose, whereas the effects of WGA and RCA-I were reversed by rinsing the zona pellucida with the respective inhibitory sugars. Thus treatment of the zona pellucida with Con A induces critical change of the molecules including D-mannose residues on the zona pellucida. Furthermore, the finding that pretreatment of spermatozoa but not oocytes with D-mannose blocked penetration of the spermatozoa indicated that D-mannose–binding structures are present on the sperm surface.

Preliminary experiments showed that none of the sugars tested, even at the highest concentrations used (0.1 mol/L) affected sperm mobility. Therefore, this blocking effect of D-mannose was not caused by a reduction of sperm mobility. Another possibility is that spermatozoal proteinases necessary for sperm penetration are inhibited by D-mannose. Anderson et al.[15] reported that human spermatozoal acrosin was inhibited by a variety of monosaccharides, especially D-fructose and D-mannose. However, they also showed inhibition of acrosin activity by D-galactose, although the inhibiting activity is somewhat low (approximately 60% of D-mannose). If the blocking effect of D-mannose on sperm penetration is caused by inhibition of acrosin activity, D-galactose should also show the blocking effect. However, this did not occur.

Blocking effects of saccharides on fertilization in other species have been reported: L-fucose in ascidians[9] and *Limulus polyphemus*,[6] L-fucose and fucoidin in the hamster and guinea pig,[10] α-methyl mannoside and D-mannose in the rat,[11] and α-methyl-mannose and sialic acid in the mouse.[12] However, results on which gamete was affected by saccharide were controversial. Consistent with our results, blocking of sperm-egg interaction by binding of saccharide residues to spermatozoa has been demonstrated in *Limulus polyphemus*,[6] the rat,[11] and guinea pig,[10] but saccharides are reported to affect the egg in the mouse[12] and both the sperm and egg in ascidians.[9] Huang et al.[10] found that in humans fucoidin blocked sperm binding to the zona pellucida and concluded that L-fucose may be part of a recognition signal between spermatozoa and eggs. We did not observe any inhibitory effect of 50 mmol/L L-fucose in the zona penetration test, but at a higher concentration L-fucose may block fertilization because fucoidin was found to be a more potent inhibitor of hamster fertilization than L-fucose.

On the basis of our results, we propose that a mandatory step in human fertilization is binding of a D-mannose–binding constituent of the sperm surface to a D-mannose residue in the sperm receptor site on the zona pellucida. Further studies at the molecular level are necessary to elucidate details of the mechanism of sperm-egg interaction.

We thank Ms. M. Ikeda for her technical assistance.

The importance of ultrasonography in infertile women with "forgotten" intrauterine contraceptive devices

Raphael Ron-El, MD, Zvi Weinraub, MD, Rami Langer, MD, Ian Bukovsky, MD, and Eliahu Caspi, MD

Zerifin and Tel Aviv, Israel

Seven cases in which an unknown intrauterine contraceptive device in situ was the cause of infertility were referred to our Infertility Clinic after each patient had been told by her physician that she no longer had an intrauterine contraceptive device. In some cases, there were lapses in the infertility workup that might explain how the cause of infertility of an intrauterine contraceptive device in situ was missed. In other cases, a thorough investigation was made and infertility treatment was started without the existence of an intrauterine contraceptive device in situ being diagnosed. (AM J OBSTET GYNECOL 1989;161: 211-2.)

Key words: Infertility, female; intrauterine devices; ultrasonic diagnosis

Reported here are seven cases of "forgotten" intrauterine contraceptive devices (IUDs) that caused infertility.

Case reports

Case 1. A 32-year-old woman was fitted with an IUD after her second delivery. Examination after 2 years showed no IUD thread through the cervix and x-ray examination did not reveal the presence of an IUD in situ. On a later occasion, an IUD was inserted, resulting in two IUDs in the uterus for 3 years. Because the woman did not conceive after the removal of the second device, she was referred to our Infertility Clinic. In the workup an ultrasonographic examination for leading follicle measurement revealed the presence of a multi-load IUD that was removed. Two months later she conceived.

Case 2. A 26-year-old woman with a 2-year history of infertility had an induced abortion at age 18. She did not recall any procedures or instructions that were given to her after the abortion. The infertility workup included a hysterosalpingogram with normal results. Because of excessive menstrual bleeding, a curettage was performed. A "homemade" IUD of nylon thread was extracted (Fig. 1). This thread was invisible on x-ray examination yet was detectable by ultrasonography. The patient conceived 6 months later.

Case 3. A 30-year-old patient had secondary infertility for 6 years. Results of a hysterosalpingogram and laparoscopy findings were normal; however, the patient reported heavier menstrual bleeding since delivery. When an endometrial curettage was performed a "homemade" nylon thread was extracted; the woman conceived 4 months later.

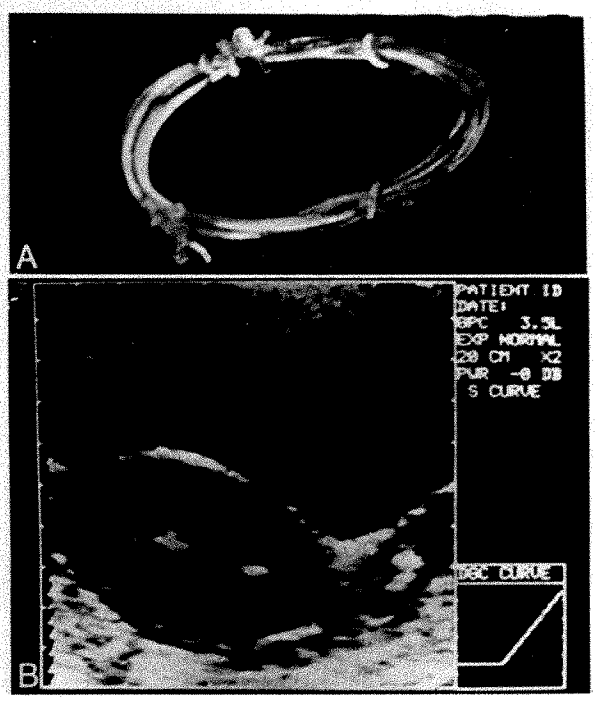

Fig. 1. Nylon thread self-made IUD (**A**) and its ultrasonographic overview in the uterus (**B**).

Case 4. A 26-year-old woman was treated for intrauterine adhesions by curettage and temporary insertion of an Ipsilon IUD. The patient recalled a second visit 2 months later for removal of the IUD. Repeated hysterosalpingogram examination did not reveal any pathologic condition. She then conceived but the pregnancy terminated in an early spontaneous abortion. At the subsequent curettage, an Ipsilon IUD (without the membrane) was found and removed. The patient conceived 2 months later.

Case 5. A 32-year-old patient had an IUD inserted after a vaginal delivery. A year later, she conceived with an IUD in situ. The physician who performed the abortion did not find the IUD. It was assumed that it had been expelled spontaneously. The patient took oral contraceptives, stopped the medication, and then did not use contraception for 2 years. A thorough investigation including hysterosalpingogram and laparoscopy had normal findings. The patient was being treated with menotropins for superovulation when an ultrasonographic examination for follicle size revealed the IUD in situ. A Cu-7 device was removed. On reexamination of the hysterosalpingogram x-ray film, the branches of the Cu-7 device were detected. Five months later she conceived.

Cases 6 and 7. Two patients, 31 and 35 years old, primiparous and secundiparous, respectively, each had an IUD inserted after delivery. When they requested removal of the devices, the thread was not seen through the cervical canal and x-ray examination gave no indication of an IUD in situ. Both patients had ultrasonographic examinations that showed an IUD in the uterine cavity; a "homemade" device and a Cu-7 device, respectively, were removed. Neither patient has yet conceived.

Comment

With widespread use of IUDs, a "forgotten" IUD in situ has emerged as a cause for infertility. This situation causes an iatrogenic infertility, prompting unnecessary noninvasive and invasive examinations and unjustified treatments. Therefore a seemingly infertile patient with a history suggestive of IUD insertion could have a "forgotten" IUD in situ. An accurate diagnosis is more often obtained by a preliminary x-ray examination rather than by hysterosalpingogram.[1] Many cases reveal devices not currently available on the market and are initially unrecognizable on x-ray films. The accuracy of ultrasonography in the diagnosis of an IUD in the uterine cavity[2] indicates its justification in the case of any infertile woman whose past history shows use of an IUD or any gynecologic intervention. Frustration, discomfort, and expense to the patient are thus minimized.

Acid-base status at birth and neurodevelopmental outcome at four and one-half years

Jennifer Dennis, DM, Ann Johnson, MD, Lesley Mutch, MD, Patricia Yudkin, MA, and Paul Johnson, MB, ChB

Oxford, England

Two hundred thirty term infants with measured acid-base status in umbilical arterial blood at birth were selected from 1210 consecutive deliveries for detailed neurodevelopmental follow-up at age 4½ years; 203 were examined. Cutoff points approximately 1 SD from the mean (pH ≤ 7.10; base deficit >12 mmol/L) were used to define acidosis. No statistically significant associations between acidosis and developmental outcome were found. The highest proportion of unimpaired children was found among those who were most severely acidotic at birth (pH ≤ 7.04; 2 SD below mean), but this finding was not statistically significant. These findings suggest that the ability of the fetus to produce an acidosis in response to the stress of labor may be beneficial to long-term outcome. The 10 nonacidotic babies with 1-minute Apgar scores of ≤3 showed statistically significant deficits in some areas. Coincident acidosis was not associated with a worse outcome for infants with low Apgar scores. (AM J OBSTET GYNECOL 1989;161:213-20.)

Key words: Umbilical arterial acidosis, neurodevelopmental outcome, Apgar score, perinatal asphyxia

Much perinatal intervention is directed toward the prevention of fetal and neonatal asphyxia in the belief that such insults may result in death or later disablement. Morbid anatomic studies have demonstrated unequivocally that events occurring during labor and delivery can lead to cerebral damage and death in the infant through the effects of trauma and asphyxia.[1] Asphyxial signs in those babies who die range from diffuse cerebral edema to cortical necrosis, boundary zone infarction, and basal nuclei damage. It is assumed that similar lesions may be present in those who survive perinatal asphyxial insults and that these lesions may give rise to a variety of neurodevelopmental problems.

There is no generally accepted definition of asphyxia. There are a number of commonly used, clinical indirect markers of asphyxia including Apgar score, neonatal neurologic state, and acid-base status at birth. None of these can be regarded as "diagnostic" of preceding hypoxia. Indeed, they may reflect other intrapartum events or even underlying and more fundamental problems of prenatal origin.[2] Historically, it should be recalled that the Apgar score was devised as an objective measurement of the condition of the neonate at birth[3] and not as a marker of asphyxia.

The notion of a simple relationship between hypoxia, acid-base status, and cerebral damage attributed to asphyxia is open to challenge.[4] Acidosis, as measured in umbilical artery blood at birth, is widely assumed to reflect fetal asphyxia. Thus it might be expected to have a relationship with the condition of the infant at delivery, neonatal neurologic status, or later neurodevelopmental integrity. Despite a remarkable lack of evidence, the strength of this belief is such that a major obstetric goal in some centers is to deliver babies with "normal" cord blood acid-base status.[5]

Sykes et al.[6] set out to measure acid-base status and Apgar scores in the umbilical cord blood of 1210 consecutively born infants delivered in the John Radcliffe Hospital, Oxford, between April and July 1981. Full data were obtained for 895 infants. About half of the missing cases arose because no member of the team responsible for collecting the blood samples was available at the time of delivery, and the remainder because blood could not be drawn from the umbilical artery. A detailed comparison between the deliveries with and without full blood gas values confirmed that the cases with full blood gas measurements were an unbiased sample of the whole.

These 895 children provided an opportunity to determine whether a single measure of acid-base status at birth in term infants would be predictive of neuro-

developmental outcome at age 4 to 5 years and form the basis of this study.

Methods

Categorization of infants by acid-base status and Apgar score. Children were assigned to study groups according to acid-base status and Apgar score at birth.

Acid-base status. From the original group of 1210 infants, 895 had full data on umbilical artery pH, base deficit, and Apgar score. From these all singleton infants born at or after 37 weeks' gestation and surviving at age 4½ years were selected ($N = 825$).

They were divided into the following four groups: (1) group A: pH ≤ 7.10, base deficit >12 mmol/L ($n = 72$); (2) group B: pH ≤ 7.10, base deficit ≤12 mmol/L ($n = 22$); (3) group C: pH > 7.10, base deficit >12 mmol/L ($n = 42$); and (4) group D: pH > 7.10, base deficit ≤12 mmol/L ($n = 689$). The cutoff levels were those used in the 1981 study and were approximately 1 SD from the mean obtained in that study.[6] Group A contained the most acidotic infants and group D the least acidotic.

All children in groups A, B, and C and a random sample of 80 from group D (group Ds) were selected for study (see "Statistical Methods"). Social class and sex are known to influence child development.[7] Thus the social class composition of group Ds was selected to match that of groups A, B, and C combined; the sample was chosen randomly from within each social class group. Social class was based on the occupation of the head of household, and five social class groups were defined: (1) professional, (2) managerial and lower professional, (3) skilled, manual, and nonmanual, (4) partly skilled, and (5) unskilled.[8] Members of the armed forces, students, and the unemployed formed a sixth group. Because the sex breakdown in group Ds matched that in the other three groups, no adjustment for sex was necessary.

Apgar score at 1 minute. Of the 24 children with a 1-minute Apgar score of ≤3, eight were in group A and two were in group B. The remainder ($n = 14$) formed group E, the nonacidotic, low Apgar score group.

Thus 230 children were selected for study (Table I); all were traced. Nine had gone abroad; four of these were in group Ds and therefore could be replaced from the total group D.

Number assessed. The general practitioners of all the children were contacted. With their permission, the parents were approached by letter, explaining the study and offering the choice of an appointment at home or in-hospital. Five physicians refused us access to their patients because of social problems in the family (one in group Ds). In addition, 17 parents (one adoptive) did not want their children assessed (13 in group Ds). Thus there were 22 refusals (14 in group Ds). We are unable to explain this excess in group Ds and acknowledge it may introduce a bias in either direction. These children were not replaced because families who refused access may constitute a special group. This left 203 children who were actually assessed (Table I).

Exclusions after assessment. After assessment there were further exclusions before analysis. Two children had suffered undoubted postnatal neurologic insults that affected their neurodevelopmental status. One was profoundly deaf after meningitis at the age of 2 years, and the other had achondroplasia and had developed hydrocephalus requiring insertion of a ventriculoatrial shunt. A third child had many dysmorphic features, suggesting organic brain disorder of prenatal origin.

The eight children whose first language was not English were also excluded, since it was clear that they were at a considerable disadvantage during testing.

Findings for 192 children were analyzed.

Assessment. A protocol was devised covering a wide range of areas of development, including perceptual, cognitive, and language skills, neurologic status, and behavioral attributes. The standardized tests used were as follows. As a basic global instrument, five of the six

subscales of the Griffiths Developmental Scales were used.[9] These were locomotor, personal/social, hearing/speech, eye-hand coordination, and performance. The test is designed for children, ages 0 to 8 years. The subscale scores are expressed in terms of developmental quotient (DQ = mental age/chronologic age × 100). The Test for the Reception of Grammar (TROG)[10] was used to assess the children's ability to understand different and increasingly complex grammatic constructions. This test is standardized in age percentiles for children ages 3 to 10 years. As a measure of behavior disorder, we used a questionnaire based on the Rutter behavior screening questionnaires.[11] These were originally standardized for children 9 to 13 years. In this study we used a modification of the parents' scale that has been developed for 5-year-old children.[12] This 15-item–rated questionnaire is filled in by the parents. Behavior disorders can be divided into conduct-type problems and neurotic-type problems.

The nonstandardized tests were as follows. For auditory discrimination, we used the Renfrew picture-pointing test,[13] which is appropriate for children from age 3½ years. Discrimination errors made during the test reflect either conductive hearing problems (secretory or acute otitis media) or centrally mediated impaired discrimination. For further testing of fine motor and visuo-motor skills, two tests were used. The Keyhole pegboard test[14] consists of a 10 by 10 cm board with 25 small, keyhole-shaped holes pointing in different directions. Into these can be slotted closely fitting pegs. The test has been standardized only for adults, and for these young children we used only the central nine holes. The task requires good fingertip and visuo-motor skills to orientate the pegs correctly and good targeting to slot them in the holes. It is a timed test performed with both preferred and nonpreferred hands. The second extra test of fine motor and visuo-motor skills required the child to draw a line between tramlines arranged to form a 4-inch square.This is a modification of one of the Frostig tests.[15] The tramlines were wide (20 mm apart) and narrow (6.5 mm apart), and the test was performed with preferred and nonpreferred hands. Scores were based on the number of errors, which were defined as touching or crossing the boundary tramlines, and on the continuity of the line drawn. For neurologic evaluation we devised a checklist. This covered specific qualitative deviations and asymmetries observed in carrying out gross and fine motor tasks used in the schedule, an evaluation of articulatory dyspraxia, and some additional neurologic "soft" signs.

Growth parameters were recorded and set against Tanner et al.[16] and Ounsted et al.[17] charts. Information was sought from the parents about the child's medical history and other social details including family structure, mother's work, and the child's preschool, playgroup, or nursery experience. Information about vision and hearing will be retrieved from routine services at a later date, some of it after school entry.

Each child was seen between the age of 4½ and 5 years by one of three developmental pediatricians (J. D., A. J, or L. M.), who did not know the original cord blood findings. Twenty percent were seen in-hospital, and the remainder were seen at home. The examiners monitored each other's performance during a short pilot study carried out to assess the feasibility and acceptability of the protocol and improve inter-observer agreement.

Statistical methods

Sample size. The number of children in groups A, B, C, and E was limited by the sample size of the original study. It was anticipated that the rate of poor outcomes in group D would be 10%.[18] Power calculations showed that a sample of 80 children from group D would be sufficient to detect a threefold increase in the most acidotic group (group A), with 85% power and at a significance level of 0.05.

Tenth percentile cutoff points. These were determined for each test from the distribution of scores for the 192 children in the study and were used for internal comparison between groups. They were not intended as population standards.

†Significant difference between group Ds and group E: $p < 0.01$.

‡Significant difference between group Ds and group E: $p < 0.05$.

Comparisons between groups. Comparisons were made initially between groups A, B, C, and Ds and then between groups E and Ds.

In comparisons between groups A, B, C, and Ds, average values were compared by means of a one-way analysis of variance; the Kruskal-Wallis version of this test[19] was used for data that were not normally distributed. Comparisons between proportions were made with the χ^2 test.

In comparisons between groups Ds and E, average values were compared with the *t* test or for data that were not normally distributed the Mann-Whitney U test. Proportions were compared with the χ^2 test.

Muliple regression analysis. Each variable was entered stepwise into the regression equation and remained in the equation only as long as its regression coefficient was statistically significant at the 0.05 level. Categoric variables, such as social class, were treated as a number of binary variables.[20]

Significance levels. This study was not designed to test a single hypothesis but rather to explore whether the groups differed in any particular areas of performance. Following convention, we have reported results as statistically significant whenever p was <0.05. However, because about 50 different significance tests were carried out, there is a very high probability that at least one spuriously "significant" result will have occurred, and a "significant" result even at the 0.01 level should be treated with caution.

Results

Some social and other factors thought likely to affect test scores are shown in Table II. There were no statistically significant differences in the distribution of these characteristics between groups.

Griffiths subscale scores. Mean scores on the five Griffiths subscales were similar across groups A, B, C, and Ds (Table III). Group E had significantly lower mean scores than group Ds on the locomotor subscale and hearing/speech subscale ($p < 0.01$ and <0.05, respectively).

Multiple regression analyses were used to identify factors showing a significant association with the Griffiths scores. Neither pH ≤ 7.10, base deficit >12 mmol/L, nor 1-minute Apgar score ≤3 were significant factors. Higher social class, playgroup, nursery, or school attendance for five or more sessions per week, female sex, and lower age at testing were statistically significantly associated with higher scores on three subscales: personal/social, hearing/speech, and eye/hand coordination. Social class alone was associated with the performance subscale score, but there were no statistically significant associations with the locomotor score. The child's place in the family, current outpatient attendance or therapy, poor hearing reported by the parent, and the place of assessment (home or hospital) were not significant explanatory factors for any of the subscale scores.

The poorest performers on all subscales (those scoring below the tenth percentile) were in general evenly distributed throughout groups A to D (Table IV). However, on the locomotor scale, only one child from group Ds (1.6%) scored below the tenth percentile compared with nine (14.5%) of the children in group A. The difference between the four groups just failed to reach statistical significance at the 0.05 level, although a direct comparison between group A and group Ds was significant ($p < 0.05$). There was no difference between the groups in the proportion of children scoring below the tenth percentile on two or more of the Griffiths

Table IV. Percentage in each group with Griffiths subscale score <tenth percentile

Significant difference between A and D_S, $p < 0.05$.

*Locomotor: one child from groups A, B, and C not tested; personal/social: one child from group C not tested; and hearing/speech: one child from group A not tested.

subscales. Although the number of children in group E is small, seven of 10 scored below the tenth percentile in one or more of the five subscales.

Keyhole pegboard test. The overall mean time for completion of the test was 60.7 seconds (SD 33.4) for the preferred hand and 69.4 seconds (SD 32.8) for the nonpreferred hand. There was no difference between groups in the mean time taken or in the number of poor performers (<tenth percentile).

Using the preferred hand, two children failed to complete the test within 3 minutes, both of whom were from group A. Using the nonpreferred hand, six children were considered failures: four of 63 from group A, one of 37 from group C, and one of 64 from group Ds.

For each child, the difference between completion times with the preferred and nonpreferred hands was calculated. There was no difference in the mean value of this measure between the five groups.

Tramline square. There was no difference in scores between groups A, B, C, and Ds. Group E scored higher (i.e., made more errors) than group Ds on both wide and narrow tramline squares and with both preferred and nonpreferred hands. The difference was statistically significant only for the narrow square, which was drawn with the nonpreferred hand ($p < 0.05$).

Rutter score. Twenty-two of the 192 children (11.5%) scored 12 or more. This is consistent with the findings of Watt et al.[12] for this modified version of the scale. There was no statistically significant difference in total Rutter scores between groups A, B, C, and Ds. However, children in group E scored significantly higher (i.e., were more behavior disordered) than those in group Ds ($p < 0.05$). The behaviors reported in this questionnaire fall into two groups that reflect either conduct-type problems (e.g., fighting, aggression, or tempers) or neurotic-type problems (e.g., shyness, fearfulness, etc.). An excess of conduct-type problems differentiated group E from group Ds.

Test for the Reception of Grammar (TROG). There was no difference between the groups in the numbers of children scoring below the tenth percentile on the Test for the Reception of Grammar.

Table V. Percentage in each group with different levels of overall impairment

*Grades**	*A* (*n* = 63)	*B* (*n* = 18)	*C* (*n* = 37)	*Ds* (*n* = 64)	*E* (*n* = 10)
1	39.7	22.2	40.5	39.1	10.0
2	28.6	22.2	24.3	29.7	30.0
3	22.2	50.0	24.3	20.3	30.0
4	9.5	5.6	10.8	10.9	30.0
TOTAL	100.0	100.0	100.0	100.0	100.0

*1, No impairment; 2, nonspecific poor performance on single items but overall appeared normal; 3, definite identified area(s) of impairment—not necessarily requiring referral; overall less severe level of impairment than grade 4; 4, definite impairment—usually requiring referral including global delay; lateralizing signs, and severe deficit in specific area.

Auditory discrimination and neurologic screening. The picture-pointing test results for auditory discrimination were invalidated by the presence of acute catarrhal upper respiratory tract conditions in many of the children at the time of testing. Despite a short pilot study, interrater reliability on the neurologic examination was not sufficiently established to allow us to present the findings with confidence.

Overall performance. Impairment codes were ascribed by consensus on review of total outcome information available for each child. Four levels of impairment were defined (Table V). The distribution of impairment codes showed no differences between groups. Of the 192 children, 21 (10.9%) were coded as definitely and significantly impaired (code 4); an additional 48 (25.0%) were considered definitely but less severely impaired (code 3).

Primary analysis: Summary. There was no statistically significant difference between groups A, B, C, and Ds, but a greater proportion of children in group A than group Ds scored below the tenth percentile on the Griffiths locomotor subscale (Table IV).

The mean score for group E was significantly lower

Table VI. Griffiths subscale scores: Groups Ds and E and acidotic low Apgar score group

	Group Ds (n = 64)	*Group E (nonacidotic; low Apgar) (n = 10)*	*Acidotic; low Apgar (n = 8)*

Performance			
Mean	111.2	110.5	104.5
SD	19.8	23.0	24.0

than that for group Ds on the Griffiths locomotor subscale ($p < 0.01$) and the hearing/speech subscale ($p < 0.05$) (Table III). Group E also did statistically significantly worse than group Ds in the narrow tramline test performed with the nonpreferred hand ($p < 0.05$). Children in group E had a significantly higher Rutter score (i.e., were more behavior disordered) than those in group Ds ($p < 0.05$).

Further analyses

Griffiths "profile." Like other investigators, we found that the population means for all five Griffiths subscales were greater than 100.[21] In addition, they differed considerably from one another (Table III). This meant that a given score on one subscale did not denote the same level of achievement, relative to other children, as the same score on another subscale. Therefore to compare relative achievement across all five subscales, the scores were standardized by being expressed as a number of standard deviations from the mean for that subscale.

Therefore consistency of performance across the Griffiths subscales could be measured for each child in two ways: by the standard deviation of the five standardized Griffiths scores and by the range. Thus children who performed consistently well (or consistently badly) on all five subscales had a small range of scores. Multiple regression analysis was used to determine factors significantly associated with consistency of performance across the five tests. All the explanatory variables previously tested were again examined. The only statistically significant factor was a 1-minute Apgar score of ≤3, which decreased the consistency between scores.

Further analysis suggested that this decrease in consistency arose because the minimum standardized Griffiths score for children with low Apgar scores was relatively depressed. The mean minimum score for the 18 children with low 1-minute Apgar score was −1.29 (SD 0.76). In other words, in the Griffiths subscale on which they performed worst, these children scored an average 1.29 standard deviations below the mean. This was significantly lower ($p < 0.02$) than the mean minimum score for the children in group Ds (−0.79: SD 0.77). There was no difference in the maximum standardized scores for the two groups: 0.94 (SD 0.86) for children with low Apgar scores compared with 0.88 (SD 0.90) for group Ds. The minimum scores for children with low Apgar scores were not concentrated in any particular area of performance.

Very acidotic children (n = 27). Since it was possible that a failure to demonstrate differences between groups A, B, C, and Ds was related to a relatively high cutoff point for pH (1 SD below the mean), those children from groups A and B with an umbilical artery pH of ≤7.04 (2 SD below the mean) were compared with group Ds (normal acid-base status).

The very acidotic children did not perform worse than those in group Ds on any of the tests. Indeed, on overall performance 52% were graded as totally unimpaired (grade 1) compared with 39% in group Ds and 28% of the less acidotic children (pH 7.05 to 7.10). Neurotic-type behavior problems were also underrepresented within this very acidotic group.

All children with Apgar scores of 3 or below. Because our results have suggested some deficit in performance among children in group E (i.e., low Apgar score at 1 minute without acidosis), the results of all infants in the cohort with Apgar scores of ≤3 (at 1 minute) (both nonacidotic and acidotic) were further analyzed. Therefore the seven infants from group A and one infant from group B with Apgar score of ≤ 3 were considered, as well as those from group E. As Table VI shows, the eight acidotic children with low Apgar scores had higher mean scores than those in group E on three subscales: locomotor, personal/social and hearing/speech. On these subscales, acidotic children

with low Apgar scores had mean scores very close to those of the control group Ds. On the two other subscales, the acidotic low Apgar score group performed somewhat worse than group E. None of the differences between the acidotic children with low Apgar scores and group E was statistically significant.

Comment

Sykes et al.[6] demonstrated that during the intrapartum period there is a poor correlation between clinical evidence of depression as measured by Apgar score and umbilical artery pH and base deficit except at the extremes of acidosis. This confirmed the original findings of James et al.,[3] which have been since corroborated by Lumley and Wood[22] and Dijxhoorn et al.[23]

The relationship between neonatal neurologic state and acid-base status at birth is equally uncertain. Dijxhoorn et al.[24] showed that umbilical artery pH had a low predictive value in detecting term infants with neurologic abnormality, although Huisjes et al.[25] pointed out that in already-compromised infants (i.e., preterm or growth-retarded infants), neonatal neurologic signs showed an association with preceding acidosis, and this may well be an important distinction.

Sheridan-Pereira et al.[26] described a syndrome of distal hypertonia, abnormal movements, and altered neonatal neurobehavior in infants with an umbilical venous pH of <7.20. In that study both Apgar score and cord venous pH were significantly, although not strongly, predictive of abnormal neonatal neurology.

This uncertainty of the significance of acid-base status in predicting neurologic status either at birth or in the neonatal period is extended to observation at subsequent follow-up. It has been assumed on the basis of limited animal experimental evidence that a severe acidotic response is associated with neurologic deficit.[27] Low et al.[28] followed up at age 5 years, 37 infants with abnormal acid-base status in umbilical artery blood at birth (buffer base <34 mEq/L). They found no cases of cerebral palsy or other major or minor neurologic handicap and no significant differences in development from that found in a control group.

In a subsequent study, at 1 year, Low et al.[29] demonstrated a gradient of major deficit among high-risk infants of varying gestational ages as metabolic acidosis in umbilical artery blood increased. A recent study by Ruth and Raivio[30] found that umbilical arterial pH <7.16 was not a good predictor of developmental abnormality at 1 year of age. Except for these studies, there is a remarkable lack of information on the late outcome of infants who were "acidotic" at birth. Touwen and Huisjes[31] found that acidemia was associated with abnormal neonatal neurologic findings, particularly in growth-retarded fetuses, but not with abnormal neurologic findings at 4 to 6 years old.

In our study 11% of the children examined had a definite impairment. This proportion is similar to that described by Brimblecombe et al.[18] As expected, we demonstrated that higher social class, female sex, and nursery school attendance were associated with significantly better performance on some Griffiths subscales.

However, our results show no relationship between umbilical artery acid-base status in term infants and poor neurodevelopmental outcome at age 4½ years. Theoretically this might have been because infants with severe acidosis at birth died and those who survived survived intact—the "all or none effect."[32] However, only three deaths occurred among the term infants in the original cohort, and these were attributable to congenital malformations. None had intrapartum acidosis.

It is interesting to compare our study with that of Ruth and Raivio.[30] The birth cohorts studied are numerically similar, but unlike ours, the Finnish study included preterm infants. Notably, the degree of acidosis at birth was minimal compared with that in the cohort on which our study was based.[6] The value of pH 2 SD below the mean was 7.16 for vaginal deliveries and 7.25 for cesarean deliveries compared with 7.04 in our hospital. A further difference was that our follow-up measures were sensitive to lesser degrees of handicap, and the children were 3 years older. This is reflected by the fact that the Finnish study, which was initially based on well-baby clinic screening, found only 5% with adverse outcome, both definite and "slight." By contrast, using our criteria 11% of the children in our group with normal acid-base status at birth (Ds) had definite impairment. An additional 20% had mild impairments that would not have been identified by less sophisticated outcome measures. Yet even with these more sensitive outcome measures, we were unable to show a relationship between acidosis at birth and later outcome.

Progressive acidosis is a physiologic response to labor. We suggest that the capacity to respond to intrapartum stress by a further acidotic shift may also be a physiologic adaptive adjustment that bodes well for future neurologic integrity. Indeed, in our study unimpaired children (coded 1) predominate among those who were severely acidotic. A similar finding was made by Ruth and Raivio.[30] Of the six children in their study who were severely acidotic at birth, only one was "slightly abnormal" at age 1 year. Therefore we speculate that the absence of an acidotic shift may be a sign of a compromised fetus. This may explain our observation that of the children who had an Apgar score of <4, those who were not acidotic appeared to fare worse in some areas than those who were acidotic. Our numbers were small, but the findings concur with those of Dijxhoorn et al.[23] These findings need to be explored further in a larger study.

Our results, if confirmed, would carry clinical and medical-legal implications. Until the relationships be-

tween the measurements that have been assumed to be indirect markers of fetal asphyxia and the ultimate neurodevelopmental outcome of the infant have been further clarified, the greatest caution must be exercised before assignment of the cause of later impairment to asphyxia as defined by these markers alone.

We are grateful to Ms. Jenny Daniels, Mrs. Jane Mitchell, and Mrs. Joan Kidd for invaluable help in tracing the children and arranging the assessments, and to Mrs. Bridget Bryant for computer programming. Dr. Adrian Grant, National Perinatal Epidemiology Unit, and Professor A. Turnbull, Nuffield Department of Obstetrics and Gynaecology, Oxford, provided helpful advice and comment. We also thank Miss Philippa Claiden, Miss Sarah Ayers, and Mrs. Olive Goddard for preparation of the manuscript.

The effect of elevated blood glucose on the electroencephalogram and cerebral metabolism during short-term brain ischemia in fetal sheep

Conrad R. Chao, MD, A. Roger Hohimer, PhD, and John M. Bissonnette, MD
Portland, Oregon

The effect of cerebral ischemia on cerebral metabolism and the electroencephalogram was studied with and without prior glucose infusion in near-term normoxic fetal sheep. At normal blood glucose levels, the electroencephalogram decreased in amplitude during ischemia. At elevated blood glucose levels the electroencephalographic amplitude was much less attenuated by ischemia although Fast Fourier Transforms revealed a shift toward slower frequencies. Under either normal or elevated blood glucose conditions, ischemia caused cerebral oxygen consumption to decrease, glucose uptake to increase, and a net efflux of lactate to occur. Elevated blood glucose appears to help maintain electroencephalographic activity during ischemia, perhaps by fueling additional anaerobic energy production. The relationship between the electroencephalogram, brain metabolism, and brain damage remains to be defined. (Am J Obstet Gynecol 1989:161:221-8.)

Key words: Fetal brain, metabolism, electroencephalogram, glucose, ischemia

Previous studies of the relationship between cerebral metabolism and the electroencephalogram (EEG) during intrauterine hypoxic-ischemic conditions have focused on the response to arterial hypoxic hypoxia, a state in which both arterial blood pressure and cerebral blood flow are elevated.[1, 2] However, Wagner et al.[3] and Ting et al.[4] have emphasized the importance of hypotension and the resultant cerebral ischemia in the genesis of the metabolic and histopathologic changes of fetal brain injury. We recently demonstrated that reducing cerebral perfusion pressure by brachiocephalic artery occlusion, while maintaining flow to most of the body, generates a state of cerebral ischemic hypoxia. The associated metabolic derangements were consistent with tissue hypoxia (low venous oxygen tension), anaerobiosis (lactate efflux), and perhaps brain glucose depletion.[5]

The studies by Myers et al.[6] in adult and juvenile animals have emphasized the adverse effect of hyperglycemia in the genesis of hypoxic-ischemic brain injury. These studies emphasized the importance of glycogen stores and tissue lactate accumulation in regions of the brain that undergo injury. Fetal and neonatal studies of hyperglycemia have not yielded consistent results. Blomstrand et al.[1] reported that hyperglycemia was associated with a decrease in cerebral oxygen consumption and a trend toward deterioration in the somatosensory evoked potential in hypoxic fetal sheep. Conversely, Mann et al.[2] reported that glucose loading had no effect on the umbilical venous P_{O_2} required to induce isoelectricity. All of these studies were carried out in fetal sheep; however, the discrepancy may be due in part to the three different end points selected: neurohistology,[6] somatosensory evoked potential,[1] and an isoelectric EEG.[2] Vannucci et al.[7] and Voorhies et al.[8] found that glucose given before hypoxia in newborn rats did not increase histologic brain injury and was associated with increased duration of survival during hypoxia. The differences between these findings and those of Myers et al.[6] may be explained in part by the different species or differences in central nervous system development at the time of study.

We have sought to test the hypothesis that in near-term fetal sheep elevations of blood glucose immediately before short-term, incomplete, global cerebral ischemia would partially prevent the attenuation of the EEG. Additionally we have attempted to determine if blood glucose elevations before ischemia would alter the cerebral uptake of glucose and oxygen or the efflux of lactate. In a previous study[5] we noted that when measurements are begun 2 minutes after fetal cerebral ischemia is instituted, oxygen consumption was de-

pressed. In this study we wished to evaluate the role of glucose availability during this period of depressed cerebral metabolism that occurs shortly after ischemia is initiated.

Material and methods

Surgical procedures. At 120 to 129 days of gestation, eight ewes of mixed Western breed were anesthetized with 7 to 10 mg/kg intravenous thiamyl sodium followed by positive-pressure ventilation with 1% halothane in 50% nitrous oxide and 50% oxygen. Hysterotomy was performed and polyvinyl catheters inserted into both fetal brachial arteries and advanced until the tips approached the brachiocephalic artery. A hind limb vein catheter was placed and advanced into the inferior vena cava. A trephine was used to remove a 1 cm circular portion of the skull in the midline to expose the sagittal sinus midway between the coronal and lambdoidal sutures. The sinus was then punctured with a needle and a polyvinyl catheter inserted caudally to the vicinity of the confluens (about 1 cm). Stainless steel electrodes (Cooner Wire, Chatsworth, Calif.) were placed supradurally 1 cm lateral to the midline at the junction of the lambdoidal and sagittal sutures through small burr holes. A left lateral thoracotomy was then performed and an inflatable occluder (In Vivo Metrics, Healdsberg, Calif.) placed around the common brachiocephalic artery, which supplies both forelimbs and carotid arteries in this species. All fetal incisions were closed and a polyvinyl catheter was sewn to the fetal skin for amniotic fluid pressure measurement.

The maternal abdomen was closed and one million units of penicillin G was deposited in the amniotic fluid. After operation animals were allowed at least 4 days to recover before any studies. Animal housing, care, and use were in accordance with the National Institutes of Health Guide for the Care and Use of Laboratory Animals.

Experimental procedures

Physiologic measurements. Ewes were allowed food and water as desired throughout the study period. The catheters were connected to strain gauges (Statham, Oxnard, Calif), which had been calibrated with mercury manometers. Mean arterial pressures were derived electronically (0.3 Hz low-pass filter, Beckman type 9853 coupler, Beckman Instruments, Fullerton, Calif.). The pressures from the brachial artery, which was distal to the occluder, and sagittal sinus were digitized; the difference (the cerebral perfusion pressure) was calculated by a computer, and the perfusion pressure was automatically regulated by changing the amount of saline solution in the balloon occluder. In this manner perfusion pressure could be prospectively specified and controlled.

Cerebral blood flow measurements. Regional cerebral blood was measured with radionuclide-labeled microspheres and the reference sample technique.[9, 10] For each blood flow determination a well-dispersed suspension of approximately 2×10^6 15 μm microspheres in 6% dextran was injected over 15 seconds into the hind limb vein followed by a flush of 3 ml saline. Reference sample blood was withdrawn from a brachial artery at a rate of 2.14 ml/min for a period beginning just before the injection and continuing for 3 minutes after injection. The isotopes utilized were cerium 141, chromium 51, strontium 85, niobium 95, and scandium 46. After completion of the experiments the animal was killed with intravenous barbiturate and phenytoin. A postmortem examination was performed to verify catheter placement and to remove the brain. The brain tissues were counted with the reference samples in a

multichannel analyzer (Model 601, Packard/Nuclear Data, Schaumburg, Ill.). Isotopic separation and blood flow calculation were performed by methods that have been previously described.[9-11]

Blood sampling and analysis. Arterial and sagittal venous blood samples (3 ml) were anaerobically obtained. Sagittal sinus blood has been validated as a means of sampling exclusively cerebral venous drainage, because extracerebral contamination is negligible.[12] Blood gas and pH determinations were made at 39° C with a model 3BGS blood gas analyzer (Radiometer, Copenhagen). Oxygen contents were measured with a Lex-O_2-Con (Lexington Instruments, Waltham, Mass.). Glucose and lactate were measured in duplicate in frozen-thawed whole blood with glucose oxidase–hydrogen peroxide and lactate oxidase–hydrogen peroxide methods (YSI 23A glucose analyzer, Yellow Springs Instruments, Yellow Springs, Ohio). The instrument was calibrated daily with standard solutions. Intrareplicate reproducibility was within 4%.

Electroencephalographic recordings. Fetal EEG signals were amplified and displayed on a strip chart recorder (model R612, 9853 coupler, Beckman) and digitized at 95 Hz with an analog-to-digital converter (Data Translation DT2801, Marlborough, Mass.) and the Labtech Notebook software (Laboratory Technologies Corporation, Wilmington, Mass.). An independent 100 μV voltage source was used for calibration. Signals were electronically filtered by a 30 Hz low-pass filter.

Fast Fourier Transforms and power spectral analyses were performed over 25-second intervals by the Fast Fourier Transform subroutine in the Labtech Notebook package. The EEG during the 25-second normotensive period immediately before the initiation of ischemia was recorded as the control recording for that experiment; the 25 seconds beginning at the time of blood sampling, approximately 2 minutes after the onset of ischemia, was recorded as the experimental EEG. Total EEG power for a given ischemic experiment was determined by summing the power spectra in 1 Hz brackets over the range 0 to 30 Hz. This was then expressed as a percent change from the total EEG power of the control recording for that experiment. Power frequency distributions were calculated by dividing the power spectra into δ-range (0 to 3 Hz), θ-range (4 to 7 Hz), α-range (8 to 11 Hz), σ-range (12 to 14 Hz), and β-range (15 to 30 Hz) and dividing the power contained in each band by the total power in that recording.

Protocol. We have previously shown that 2 to 5 minutes of ischemia produces a decrease in cerebral oxygen consumption and an efflux of lactate from the fetal brain[5]; therefore a similar short-term protocol was used. After control measurements of cerebral blood flow, blood gases, and arterial and sagittal venous glucose and lactate, animals were randomized to receive either a 10 ml infusion of 7.5% glucose in saline solution in the hind limb vein or saline solution only. The EEG recording was then begun and the infusion given intravenously over 1 minute. After 1 minute the balloon occluder was inflated to reduce cerebral perfusion pressure to approximately 10 mm Hg. After 2 minutes of ischemia, arterial and venous samples were taken, the EEG recorded, and another microsphere measurement was made. The balloon occluder was then released. After at least a 2-hour interval, the experiment was repeated with the alternative treatment. In a number of the animals the ischemic experiments were repeated in the reverse order.

Calculations and data analysis. Metabolic fluxes were calculated as the product of arteriovenous difference times the cerebral blood flow. The glucose/oxygen molar quotient was calculated as six times the glucose uptake divided by the oxygen uptake. The glu-

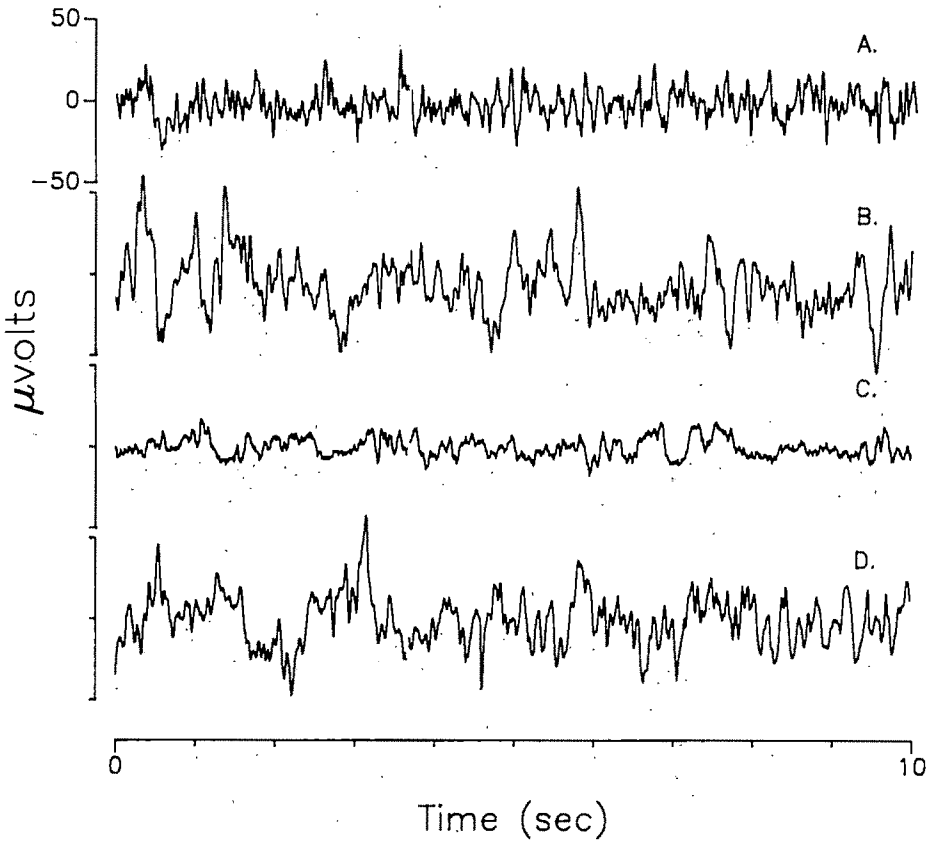

Fig. 1. EEG recordings from fetus during control conditions in low-voltage *(A)* and high-voltage *(B)* states. EEG amplitude is greatly attenuated after 2 minutes of cerebral ischemia at normal blood glucose levels *(C)* but is much less attenuated if blood glucose levels were elevated before ischemia *(D)*.

cose/lactate/oxygen molar quotient was calculated as the quantity six times the glucose uptake minus two times the lactate efflux divided by the oxygen uptake. Grouped means and SEMs between control (no occlusion), ischemic, and elevated blood glucose ischemic conditions were calculated for the eight control measurements and for 13 normoglycemic ischemic and 10 elevated glucose ischemic experiments. Statistical significance of continuous data was inferred by analysis of variance followed, when indicated, by post hoc least significant difference tests. Significance for data that were not normally distributed was determined by Kruskal-Wallis analysis of variance by ranks and χ^2. Spearman rank order correlation was performed to correlate EEG changes with the metabolic and blood chemical measurements.

Results

Metabolic measurements. Blood gas tensions, blood glucose concentrations, and blood lactate concentrations are presented in Table I. The arterial blood gas tensions and lactate concentrations were comparable and not different from control under both ischemic conditions. As shown in Table II, perfusion pressure and blood flow were significantly reduced by the balloon occlusion to approximately 25% of control in both normal and high blood glucose ischemic conditions. During ischemia, the widened arteriovenous difference for oxygen content resulted in significant decreases in venous oxygen content and Po_2, reflecting the ischemic hypoxia with glucose and nonglucose experiments being similarly affected. The arteriovenous difference for glucose widened during ischemia to approximately 0.8 mmol/L in both cases. Whereas venous glucose fell to 0.46 mmol/L in normoglycemic ischemia, when arterial glucose was high, the sagittal venous (outflow) blood from the brain maintained a value (1.69 mmol/L) in excess of the control arterial glucose concentration (Table I).

Oxygen consumption (Table II) decreased significantly between control and both ischemic groups. The ischemic groups were not different from each other. There was an increase in glucose uptake that did not reach significance; glucose-infused and saline solution–infused means were essentially the same. Mean lactate efflux was significantly increased above control in both

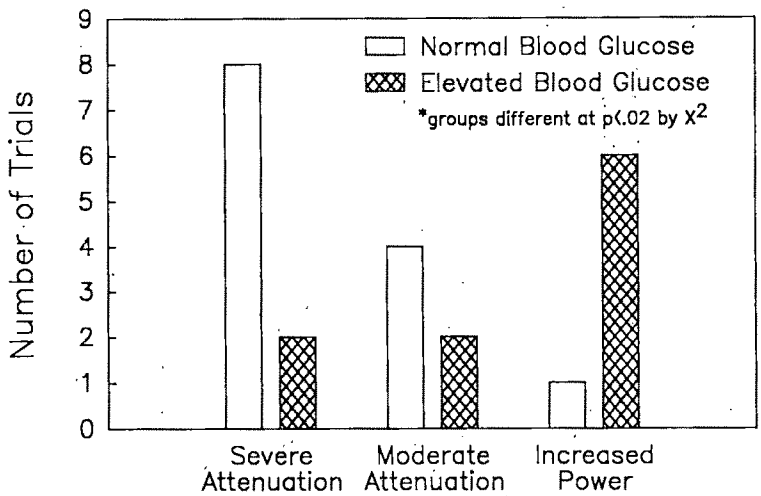

Fig. 2. Elevation of blood glucose before ischemia increases total EEG power during ischemia relative to normoglycemic ischemia.

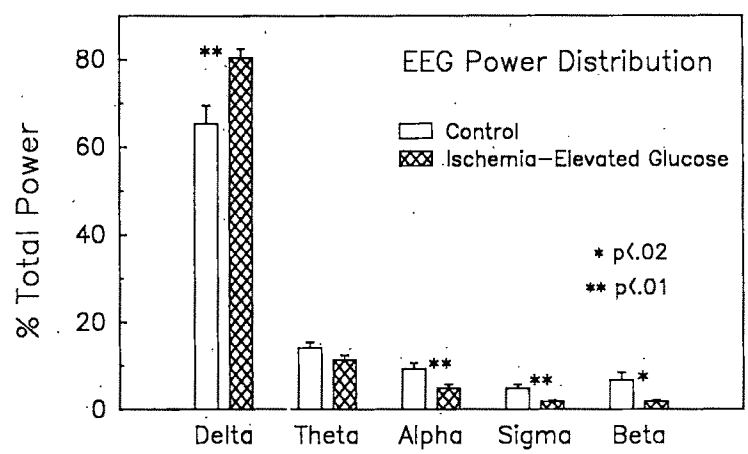

Fig. 3. Cerebral ischemia after elevation of blood glucose concentrations was associated with a shift of power toward slower frequencies.

ischemia groups, and they were not significantly different from each other. The glucose/oxygen quotient was significantly increased above control in both ischemia groups and they likewise did not differ from each other. Similarly, the glucose/lactate/oxygen quotient was significantly increased above control in both ischemia groups but was not different between the hyperglycemic and normoglycemic ischemic groups.

Electroencephalographic findings. A series of digitized recordings from a typical animal are presented in Fig. 1. The high- and low-voltage electrocortical states[13, 14] can be easily distinguished. Both ischemic periods were initiated from the low-voltage state. To the naked eye, the amplitude of the EEG of the elevated glucose ischemic experiment clearly exceeds that of the normal blood glucose ischemia; summation of frequency bands for total power determination demonstrates that the elevated blood glucose tracing contains 371% of control power, whereas the normoglycemic recording exhibits only 33% of control power. Thus in this example the administration of glucose appears to preserve electrocortical function during cerebral ischemia. It is difficult to distinguish the elevated glucose ischemia from the high-voltage control with respect to amplitude or apparent frequency distribution.[14]

Because the total power percent changes from control were not normally distributed, they were analyzed in a nonparametric manner by dividing them into three groups: a >50% increase from control power (severe attenuation), a <50% decrease from control (moderate attenuation), or an increase relative to control (increased power). Fig. 2 depicts the changes in power expressed in terms of glucose status; the tendency for prior glucose infusion to maintain or augment EEG amplitude and power during ischemia was highly significant.

Table III. Cerebral metabolism with alterations in EEG during ischemia

	Increased power	*Moderate attenuation*	*Severe attenuation*
Cerebral blood flow* (mg/min/100 gm)	37 ± 3	38 ± 3	28 ± 4
Oxygen consumption† (μmol/min/100 gm)	109 ± 6	109 ± 9	87 ± 9
Glucose consumption (μmol/min/100 gm)	26 ± 2	30 ± 3	23 ±3

Arterial oxygen content (mmol/L)	3.8 ± 0.2	3.6 ± 0.3	4.0 ± 0.2
Venous oxygen content (mmol/L)	0.8 ± 0.1	0.7 ± 0.1	0.7 ± 0.1
Arterial glucose (mmol/L)	2.1 ± 0.2	1.6 ± 0.4	1.7 ± 0.2
Venous glucose† (mmol/L)	1.4 ± 0.2	0.8 ± 0.3	0.8 ± 0.2

*$p < 0.03$, Spearman rank order correlation.
†$p < 0.07$, Spearman rank order correlation.

During ischemia there was a significant decrease in power in higher-frequency bands and an increase in the lower-frequency bands relative to control in the glucose-infused group (Fig. 3); this effect was not statistically demonstrable in the normoglycemic ischemia group.

The EEG and metabolism. Table III presents metabolic fluxes for the EEG subclasses. Change in total EEG power was significantly correlated with cerebral blood flow, oxygen consumption, and venous glucose concentration, although the correlations with oxygen consumption and venous glucose were of borderline significance. There was, however, no correlation between EEG functional class and venous oxygen content, glucose uptake, or lactate efflux.

Comment

We have demonstrated that elevations in blood glucose before cerebral ischemia maintain EEG amplitude and power when compared with normoglycemic ischemia. Additionally, when glucose was elevated, the proportion of the power in slower frequency bands increased during ischemia, while that in faster frequency bands decreased.

During ischemia, oxygen consumption fell while glucose uptake increased, and a net lactate efflux was observed. Because arteriovenous differences for glucose and oxygen increase during ischemia, the venous concentrations fall. Thus venous blood and perhaps brain tissue were both hypoxic and had low concentrations of glucose during ischemia in the absence of a glucose infusion. These findings confirm our previous observations of severe ischemia.[5] In this current study there were no significant differences between prior glucose-infused and saline solution–infused ischemic trials with regard to these metabolic parameters, although there was a trend toward greater lactate efflux with elevated glucose. The ischemic glucose/oxygen quotient was greater than unity in either glucose condition, indicating that more glucose was taken up than could be oxidized by the measured consumption of oxygen. Thiringer et al.[15] noted a similar relationship between glucose/oxygen quotient and deterioration in somatosensory evoked potential during hypoxemia; a mild impairment was associated with quotients of 1.42 to 1.43, whereas severe impairment was associated with a quotient of 2.1.

Even when the measured lactate efflux is accounted for with the glucose/lactate/oxygen quotient, a portion of glucose uptake is stoichiometrically unaccountable, suggesting that lactate production may exceed the measured efflux because of membrane transport limitations, as we have previously speculated.[5] It should be noted, however, that a recent study has shown that brain lactate levels measured by in vivo nuclear magnetic resonance spectroscopy were not elevated in newborn lambs given a glucose infusion after 20 minutes of brain ischemia.[16] Glucose infusion failed to elevate brain lactate above that seen in noninfused ischemic lambs despite an increase in glucose arteriovenous differences.

Taken together, these observations suggest that during cerebral ischemia, oxygen consumption and glucose oxidation are inadequate to meet the needs of the cells; glucose uptake increases to fuel anaerobic glucose metabolism, resulting in production and net efflux of lactate. Energy production from this excess glucose is limited to anaerobic glycolysis. In the normoglycemic conditions, EEG power could not be maintained despite these adaptations.

Glucose infusion before ischemia did not enhance glucose uptake or lactate efflux during ischemia, al-

though it may have increased lactate production and improved electroencephalographic function. It is important to note that the Fick technique measures net fluxes of substrates rather than metabolic rates. There will be a close relationship between net fluxes and metabolic rates for substrates that cannot be stored in tissue, such as oxygen, whereas metabolic rates for substrates such as carbohydrates will be the sum of net flux and net change in the tissue pool. Although we did not measure tissue concentrations, it is likely that the tissue concentration of glucose before the initiation of ischemia was increased by the glucose load. Thus endogenous stores of glucose were probably greater after glucose loading.

The amount of endogenous stores becomes important because venous concentrations of glucose in these experiments become very low in normoglycemic ischemia because of the combined effects of the increase in net influx and the decrease in blood flow. Previous studies of metabolite concentrations in the fetal sheep cerebral cortex during combined hypoxia-hypotension demonstrated a whole tissue extract glucose concentration of 0.44 mmol/kg, which is slightly less than our measured venous concentration.[3] It is interesting to note that venous oxygen contents were the same in all three classes of EEG impairment, whereas venous glucose concentration was significantly higher when function was preserved than when experiments were done in which the EEG was attenuated (Table III). This suggests but does not establish that the low glucose concentration, rather than the low oxygen concentration, limited neural function. Furthermore, the low glucose concentration may have limited tissue lactate production during normoglycemic ischemia.

Elevations in blood glucose may then help maintain electrical activity during ischemia because of anaerobic glycolysis of the increased stores. This would also explain the trend toward increased efflux of lactate. Therefore direct measurement of the tissue concentrations would be necessary to confirm these speculations.

Our data conflict with those of Blomstrand et al.[1] and Mann et al.,[2] who reached other conclusions regarding the effect of glucose loading on the EEG during intrauterine hypoxia-ischemic conditions. Blomstrand et al. studied anesthetized fetal sheep during maternal hypoxia. On a scale of 0 to 5, with 5 representing the most severe deterioration of somatosensory evoked potential, arterially hypoglycemic fetal sheep (0.5 mmol/L) demonstrated a mean score of 1.22, whereas in hyperglycemic fetuses (2.25 mmol/L) the mean value increased nonsignificantly to 1.88. Oxygen consumption in this experiment fell to 48 μmol/min/100 gm, suggesting a more severe derangement of metabolism. Spontaneous EEG results were not reported. Mann et al. studied anesthetized fetal sheep during maternal hypoxia and found that the arterial Po_2 at the onset of isoelectricity was not different between elevated blood glucose and euglycemic fetuses. However, because cerebral blood flow and metabolism and cerebral venous oxygen tensions were not studied, it is not possible to compare the severity of the hypoxic insult with that of our experiment. The fact that all fetuses became isoelectric in that experiment suggests that the insult was more severe.

Hypoxic slowing of the EEG has been described in human adults[17] and in fetal sheep.[18] We were able to statistically demonstrate this effect in fetuses with elevated blood glucose levels. As noted in the Results section, a similar trend was observed during normoglycemic ischemia. It is also difficult to precisely characterize the frequency composition of a near-isoelectric waveform with Fast Fourier Transform.

Interestingly, Ishikawa and McDowell[19] found that electrical activity in lightly anesthetized, normoxic, hypotensive cats approached isoelectricity at cerebral blood flows of about 20 to 25 ml/min/100 gm, close to the severely affected EEG class in this experiment. Other investigators[20] have found the critical flow threshold to be closer to 15 to 20 ml/min/100 gm in adults. It is possible that in fetal animals the lower arterial oxygen concentration causes loss of function at higher blood flows during ischemia.

Although we could not differentiate the "increased power" recordings from those of a typical control high-voltage state, visually or with Fast Fourier Transform analysis, the metabolic measurements differed from that of typical high voltage. Oxygen consumption was reduced to a mean of 109 μmol/min/100 gm, and a lactate efflux of 7.5 μmol/min/100 gm was detected; the stoichiometry of the measured fluxes implies that anaerobic consumption of glucose occurs. This suggests that the high-voltage state previously described during hypoxia[21] may be metabolically distinct from the high-voltage state observed during normoxia.

It is not clear whether it is beneficial to maintain EEG amplitude and power in the face of tissue hypoxia-ischemia. Duffy et al.[22] have suggested that the depression of function during severe hypoxia may represent a protective mechanism to conserve energy, perhaps because of a decrease in oxygen consumption. It is also possible that low tissue concentrations of glucose may also act as a protective signal to prevent either further energy expenditure, lactate production, or both. The studies of Myers et al.[6] suggest that, at least in adult and juvenile animals, glucose administration is associated with histologic evidence of brain damage after hypoxia. For these reasons we would strongly recommend that no clinical inference be made from this study until more is known about the relationship between

glucose concentrations and brain damage. Clearly, there is a need for further study of the complex interaction of brain function, metabolic substrates, oxygen, and blood flow in the genesis of brain injury during development.

In conclusion, we have demonstrated that elevated blood glucose before noncomplete fetal brain ischemia maintains EEG power whereas power is lost during normoglycemic ischemia. This suggests that substrate availability may limit energy metabolism during severe cerebral ischemia in the sheep fetus. Anaerobic metabolism of increased endogenous tissue stores of substrate may support the persistent electrical function observed during ischemia after prior glucose infusion. Further study with measurement of tissue concentrations of carbohydrate substrates will be necessary for confirmation.

The assistance of Sharon Knopp, Neil Notaroberto, Keri Stepper, and Gail Willeke is greatly appreciated.

Uncoupling of excitation from contraction in uterine smooth muscle in near-term ewes

Deborah L. Reid, PhD, Mark C. Hollister, MD, Susan R. Davidson, MD, Terrance M. Phernetton, BS, and John H. G. Rankin, PhD

Madison, Wisconsin

We infused forskolin in 30% ethanol or 30% ethanol systemically in seven chronically catheterized near-term sheep to determine the response of ovine uterine musculature to cyclic adenosine monophosphate stimulation. Maternal and fetal arterial pressures, fetal venous pressure, intrauterine pressure, and uterine electromyogram activity were monitored continuously. Prostaglandin E_2 was infused at a delivery rate that caused a minimal 5 mm Hg increase in intrauterine pressure with definite contraction-like pressure spikes and associated uterine electromyogram activity. Forskolin (10 mg in 30% ethanol) or ethanol (vehicle) was then infused for 20 minutes. The prostaglandin E_2 challenge was repeated 3 minutes later and again every 30 minutes over a 2½-hour period. Data were analyzed by repeated measures analysis of variance. Infusion of ethanol ($n = 2$) had no apparent effect on either the intrauterine pressure or the uterine electromyogram response to prostaglandin E_2 challenge. Forskolin infusion ($n = 5$) caused an attenuation of the intrauterine pressure response to prostaglandin E_2 for 93 minutes. This effect was greatest 33 minutes after the infusion ended when the integrated pressure signal was 37% of the initial prostaglandin E_2 response. The forskolin infusion had no effect on uterine electromyogram response to prostaglandin E_2. We conclude that forskolin causes an uncoupling of excitation from contraction in the intact near-term ovine uterus. (AM J OBSTET GYNECOL 1989; 161:229-33.)

Key words: Tocolysis, forskolin, cyclic adenosine monophosphate, sheep, pregnancy

Forskolin, the extract of an herb indigenous to India, is a direct stimulator of adenylate cyclase. Recently, we have shown that forskolin is capable of vasodilation of the mature ovine placenta on both the maternal and fetal sides.[1, 2] We also have shown a similar effect on rabbit maternal placental vessels.[3]

Forskolin has been shown to diminish spontaneous contractions in rat myometrial strips.[4] This event has also been demonstrated in the rat and rabbit myometrium in which relaxation was linked to increased cyclic adenosine monophosphate (cAMP) levels.[5, 6] We devised an experiment to determine whether forskolin can diminish the contractile response of ovine uterine smooth muscle to a controlled uterine stimulus. We measured both uterine electromyogram and intrauterine pressure in response to repeated prostaglandin E_2 (PGE_2) challenges to determine which, if either, measurement was affected by a forskolin-induced increase in uterine smooth muscle cAMP.

Methods

Animal preparation. Surgery was performed on seven pregnant ewes at 125 days' mean gestational age. Intramuscular ketamine (10 mg/kg) and atropine (10 μg/kg) were administered to induce anesthesia and reduce tracheal secretion. Anesthesia was maintained throughout surgery with intravenous ketamine infused through a jugular vein catheter. Surgery was performed in accordance with our standard procedure.[7] A fetal hind limb was exposed through a midline laparotomy and hysterotomy. Catheters were inserted into the hind limb artery and vein; the tips were advanced to the abdominal aorta and inferior vena cava, respectively. A catheter with side holes was attached to the fetal skin to monitor intrauterine pressure and the uterine incision was repaired. Three electrode wires were anchored in the myometrium to record the uterine electromyogram. Catheters were placed bilaterally in the maternal femoral arteries and advanced 20 cm. A final catheter was placed in the maternal right carotid artery and advanced to a position inside the left ventricle; placement was confirmed at surgery with a pressure transducer. Antibiotics were administered to the fetus (Chloromycetin, 100 mg/kg), intrauterine space (penicillin, 600,000 units), and ewe (penicillin, 400,000 units, intramuscularly). The catheters and electrode leads were exteriorized through the maternal flank and

stored in a cloth pouch. The laparotomy was then closed. The maternal jugular vein and left ventricular catheters were secured to the neck with a loosely wrapped elastic bandage. The ewe was placed in a pen with free access to food and water during the 5-day recovery period.

Experimental protocol. The ewe was moved to the laboratory on the day before the experiment. The morning of the experiment a 1 ml arterial sample was taken for analysis of blood gas tension and pH on an Instrumentation Laboratory System 1302 pH/blood gas analyzer (Lexington, Mass.). Measurements were recorded at 37° C and converted by algorithm to equivalent values at 39° C. Fetal arterial and venous pressures, intrauterine pressure, uterine electromyogram, and maternal arterial pressure were recorded with use of pressure transducers (Gould P23XL), Pidas data acquisition system, and Beckman 711 chart recorder. Analog signals were digitized on line. Both the analog and digitized signals were stored on magnetic tape.

PGE_2 (Sigma) and forskolin (Calbiochem) solutions were prepared on the morning of each experiment. Forskolin (10 mg) was dissolved in 7.5 ml of 95% ethanol and mixed with 0.9% saline solution to a final volume of 25 ml. PGE_2 was diluted with saline solution from a stock solution.

PGE_2 (0.012 ± 0.002 mg/min) was infused into the left ventricle for a 3-minute period. An acceptable response to PGE_2 was defined, according to the criteria of Nathanielsz et al.,[8] as an increase in intrauterine pressure ≥5 mm Hg and increased uterine electromyogram activity longer than 4 minutes in duration. If these criteria were not met, the PGE_2 challenge was repeated after a 30-minute period at a higher infusion rate. Generally, a response was seen with the first challenge (0.01 mg/min) but on one occasion the infusion rate had to be increased (0.02 mg/min).

Seven minutes after a successful PGE_2 challenge forskolin (10 mg diluted in 25 ml of 30% ethanol) or vehicle (25 ml of 30% ethanol) was then infused through the maternal left ventricular catheter over a 20-minute period. Three minutes after the forskolin or vehicle infusion was stopped a second PGE_2 challenge was made (T = 3). PGE_2 infusion was repeated every 30 minutes for 2 hours (T = 33, 63, 93, 123, 153).

At the end of the experiment the ewe and fetus were killed with a lethal injection of euthanasia solution (T-61, Hoechst), followed by intracardiac injection of saturated potassium chloride.

Forskolin dosage for this experiment was extrapolated from in utero work on myometrial contractility using 0.2 to 5.0 μmol/L forskolin.[5] The lipid-soluble drug should distribute evenly throughout the maternal and fetal tissues. By use of an estimated body weight of 50 kg, we calculated that 10 mg of forskolin (molecular weight = 410 gm) would result in a final concentration of approximately 0.5 μmol/L forskolin.

Data analysis. The digital tape was read with use of a VAX 8600 mainframe computer. Electrical output signals were converted to appropriate pressure readings with calibration signals recorded on tape. Data files were then imported to local IBM computers and stored on hard disk. Data files were split into separate PGE_2 infusion periods: control, 3 minutes, 33 minutes, 63 minutes, 93 minutes, 123 minutes, and 153 minutes. Polygraph records were examined to determine the time of the start and finish of each period of electromyogram activity and intrauterine pressure response. Electromyogram and intrauterine pressure values were referred to the average value preceding PGE_2 infusion for each period. Average values were computed for each period of activity. Integrated values were calculated by summing each 5-second value during a response. This calculation was made to assess the combined effects of magnitude and duration of each response. Fetal arterial pressure (referred to venous

pressure), maternal arterial pressure, and heart rate were calculated for each episode. The magnitude of the electrical signal from the uterine electromyogram electrodes varied with each sheep, depending on the placement and orientation of the electrodes on the uterus. To correct for interanimal variations, electromyogram signals were normalized so that the magnitude of each control signal was equal. The same correction factor was used for each measurement in an individual animal.

Data were analyzed with repeated-measures analysis of variance at the $p \leq 0.05$ level of significance. Differences between test values and control were accepted as significant ($p \leq 0.05$) when the overall analysis of variance test was significant.

Results

Experiments were performed on seven pregnant ewes on the one hundred thirtieth day of gestation. Arterial oxygen tension (103 ± 4 mm Hg), carbon dioxide tension (35.3 ± 2 mm Hg), pH (7.456 ± 0.02), and hematocrit (28% ± 2.1%) were all within normal range for this laboratory. There were no apparent differences between ewes in the forskolin and vehicle studies and the ewes appeared to be healthy.

Vehicle infusion. In two pregnant ewes, intrauterine pressure and uterine electromyogram responses to PGE_2 challenge were measured before and after an infusion of a 25 ml solution of 30% ethanol. Prostaglandin E_2 challenges were made every 30 minutes for 2½ hours after the infusion. There was no difference in either uterine electromyogram or intrauterine pressure response to PGE_2 at any time during the experiment.

Forskolin infusion. In five pregnant ewes, maternal and fetal arterial pressure, intrauterine pressure and uterine electromyogram responses to PGE_2 were determined before and after an infusion of 400 μg/ml forskolin in 30% ethanol solution. Maternal and fetal arterial pressures were measured continuously throughout the experiment and did not demonstrate a significant change from control values at any time during the study. Mean maternal and fetal arterial pressures measured during the control period were 93 ± 4 and 46 ± 2 mm Hg, respectively.

The intrauterine pressure response to PGE_2 challenge was compared before and at 30-minute intervals after forskolin infusion. Immediately after the forskolin infusion (T = 3 minutes), the magnitude (both integrated signal and average) of the intrauterine pressure increment was sigificantly lower than control (Table I). This effect was maximized 33 minutes after forskolin infusion when the integrated and average intrauterine pressure responses were 37% and 44% of control values, respectively. The response to PGE_2 challenge continued to be significantly lower than control levels through the 63- and 93-minute PGE_2 challenges and returned to control levels after 123 minutes. These data are presented as the percentage of control levels in Fig. 1 for both intrauterine pressure and uterine electromyogram response. The duration of the pressure responses did not change from the control value of 377 ± 51 seconds. Data from one animal are presented in Fig. 2, which illustrates the normal electrical and contractile responses to PGE_2 before forskolin, the abolition of the pressure response after forskolin, and the gradual return toward the control condition.

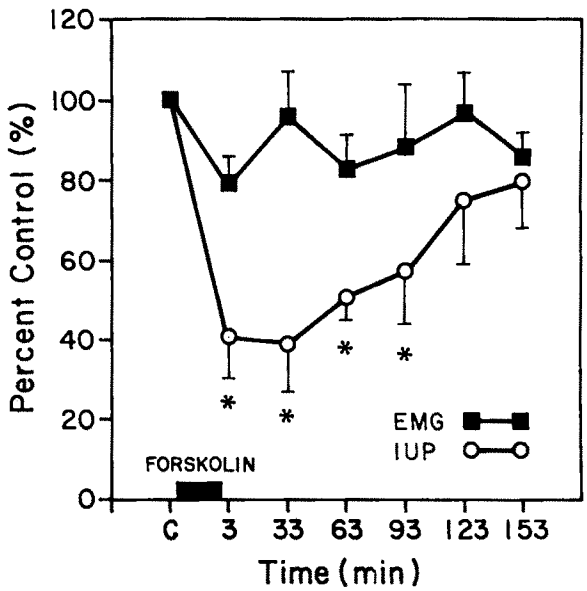

Fig. 1. Effect of forskolin on integrated uterine electromyogram and intrauterine pressure responses to PGE_2 before *(C)* and after forskolin infusion (3 through 153 minutes). Because of electrical failure, $N = 4$ for uterine electromyogam response at 3 and 33 minutes; $N = 5$ for all other data points. *Asterisk* denotes a difference from control values ($p \leq 0.05$).

On two occasions contractile-like intrauterine pressure increments were seen in the absence of electromyogram activity. These were interpreted as electrical failures; the data were not included in the final analysis.

The uterine electromyogram response to PGE_2 challenge showed no changes throughout the experiment. Both the integrated signal and the average voltage remained constant for each animal. The duration of the electromyogram response did not change from its control value of 381 ± 43 seconds.

Comment

Data from seven pregnant ewes were included in this study of the effects of forskolin on the uterine response to PGE_2 challenge. Maternal arterial blood gas tensions and pH, general appetite, and alertness all indicated that the ewes were in good condition. Therefore it is

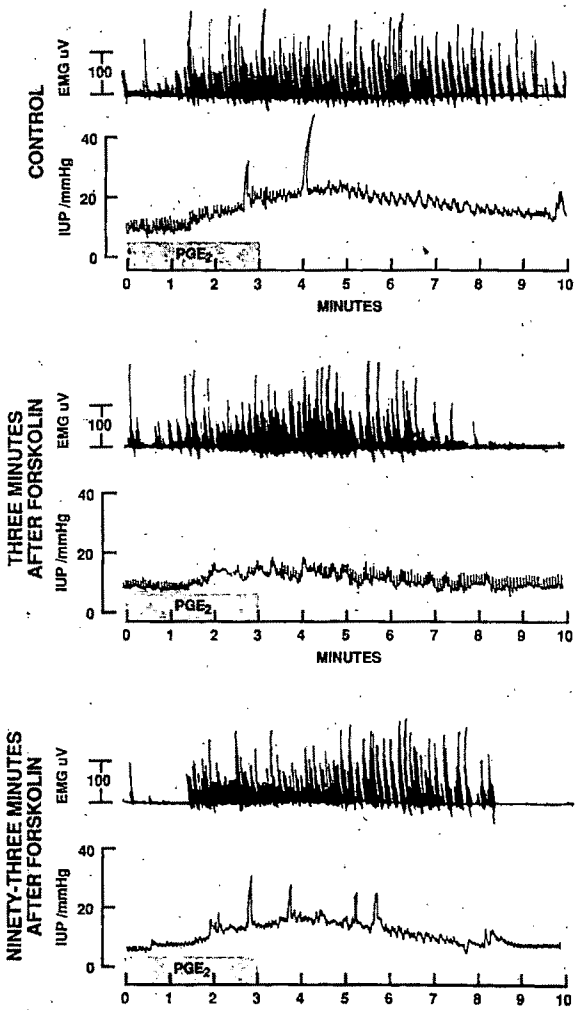

Fig. 2. Effect of forskolin on contractile and electrical responses to PGE_2 challenge in a single animal. Raw data are shown for control condition and for 3 and 93 minutes after forskolin administration. The uterine electrical activity is presented in *upper tracing* and intrauterine pressure *(IUP)* in the *lower panel.*

believed that the data herein constitute a normal physiologic response.

Prostaglandin E_2 was used in this study to stimulate uterine contractions. Prostaglandin E_2 was favored because of its immediate and well-defined effect on the uterus. Both uterine electromyogram and intrauterine pressure responses were apparent within 2 minutes of the onset of PGE_2 infusion. These indicators usually returned to normal within 10 minutes after the PGE_2 infusion was terminated. Intravenous oxytocin infusion is the standard method of labor induction in the clinical realm.[9] This hormone was used in a preliminary study but gave a protracted and irregular response that was deemed unsuitable for quantitative analysis.

This study demonstrates an attenuation of the intrauterine pressure response to PGE_2 challenge in the face of a continued normal uterine electromyographic response after systemic administration of forskolin to the late gestation ewe. Since intrauterine pressure is a physiologic marker of uterine contractility and uterine electromyogram is a marker of uterine electrical activity, this study demonstrates a disruption of the normal excitation-contraction coupling of uterine smooth muscle mechanisms. This dissociation of mechanical contraction from electrical stimulus is a smooth muscle phenomenon that has also been observed in some cases in response to isoproterenol challenge.[10]

The use of intrauterine pressure to interpret uterine contractile activity has been questioned.[8] The amniotic fluid around the late gestation fetus is no longer confluent and an intrauterine pressure catheter does not always accurately reflect an overall change in uterine tone because the pressure from a contraction may be absorbed by the fetus and fail to reveal a pressure increment. There are two reasons this was not considered a major difficulty in this study. First, only those ewes that showed a response to PGE_2 before forskolin infusion were studied. In addition to yielding baseline data, this PGE_2 challenge demonstrated that the intrauterine catheter was functioning well. Second, the consistency of the results suggests that catheter function was not affected during the subsequent 3 hours by random fetal movements.

The possible contributions of the alcohol vehicle to the tocolytic activity demonstrated for forskolin were explored in two near-term ewes. Each ewe received an intravenous infusion of 25 ml 30% ethanol over a 20-minute period. As in the forskolin series, PGE_2 was administered systemically before the infusion and at 30-minute intervals for 2½ hours after the infusion. No effect of the ethanol was apparent on either the intrauterine pressure or uterine electromyogram response. This is most likely attributed to the small quantity of alcohol involved. Doses of ethanol used to effect tocolysis in a clinical setting are more than 20 times greater per kilogram of weight and are administered over much longer periods of time.[11-14]

The molecular basis for the actions of forskolin on smooth muscle remains unclear. Forskolin, a diterpene isolated from the native Indian herb *Coleus forskohlii,* is a direct stimulant of the catalytic subunit of adenylate cyclase.[15] The subsequent rise in cAMP levels has been associated with smooth muscle relaxation in many isolated systems including swine carotid artery, rat aortic rings, and rat myometrial strips.[4, 5, 16-18] Three mechanisms have been proposed for cAMP-mediated smooth muscle relaxation: (1) decreased net calcium ion influx, (2) phosphorylation of calmodulin-dependent myosin light chain kinase, and (3) increased intracellular calcium ion sequestration.[19] Gerthoeffer et al.[16] report that forskolin can relax carotid artery strips with no change

in levels of myosin phosphorylation. This response suggests there is no change in phosphorylation of myosin light chain kinase. However, the role of myosin phosphorylation in smooth muscle relaxation remains controversial. Further reports suggest that forskolin acts by altering intracellular levels of calcium ion, either by internal sequestration or by changes in net calcium ion influx.[17, 20]

The electrical wave reflected in the uterine electromyogram is largely a function of net calcium ion flux across the plasma membrane of uterine smooth muscle cells.[21] The response of the uterine electromyogram to PGE_2 did not change at any time after forskolin infusion. It is therefore unlikely that forskolin causes smooth muscle relaxation by influencing net calcium ion influx during excitation. We surmise that forskolin causes uterine smooth muscle relaxation by causing increased formation of intracellular cAMP, which in turn elicits an increase in intracellular calcium ion sequestration, or by provoking phosphorylation of myosin light chain kinase.

In summary, systemic forskolin infusion caused a decreased contractile response without affecting uterine electrical activity in response to PGE_2 in five near-term pregnant ewes. This study demonstrates that forskolin can influence uterine response to a contractile stimulant such as PGE_2 by an intracellular event independent of cellular excitation.

Gestational diabetes in the BHE rat: Influence of dietary fat

Juliana M. Bue, BS, Dorothy B. Hausman, PhD, and Carolyn D. Berdanier, PhD
Athens, Georgia

Two studies were performed to assess the effects of fat feeding on glucose tolerance before, during, and after gestation of BHE rats. In the first study 5% or 22% fat diets were fed from 3 weeks before mating until after gestation. In the second study, these diets were fed from weaning until 400 days of age. Glucose tolerance before and after gestation was not affected by diet in the short-term study. At 19 days' gestation, glucose tolerance had deteriorated in the pregnant rats that were fed with 22% fat diet. In the long-term study, abnormal glucose tolerance was observed before mating in rats that were fed the 22% fat diet. Tolerance improved during gestation and post partum, but still was not normal. Fertility and pup survival were significantly (50%) reduced in rats that were fed the 22% fat diet. These findings suggest that either short-term or long-term feeding of a 22% fat diet to BHE rats results in a model for human gestational diabetes that might be worthy of further study. (AM J OBSTET GYNECOL 1989;161:234-40.)

Key words: BHE rats, glucose tolerance, gestational diabetes, fertility, neonatal survival

Gestational diabetes mellitus, or glucose intolerance with recognition of onset during pregnancy, occurs in approximately 1% to 3% of all pregnancies in human beings.[1-3] It is associated with an increase in fetal and neonatal death as well as with an increase in fetal weight. The risk of maternal death is also increased and it is thought that women at risk for diabetes have more spontaneous abortions and more difficulty with conception. Its pathophysiology is poorly understood, in part, because of the lack of a small inexpensive animal model to use to study the disorder.

The BHE strain of rat has many of the features commonly associated with human adult onset noninsulin dependent diabetes mellitus. It is hyperinsulinemic early in life[4] but this hyperinsulinemia subsides as the pancreas loses its ability to respond to a glucose challenge. Peripheral insulin resistance is also observed in these rats, with compensatory changes in glucose metabolism in the liver.[4-8] These changes include an increase in hepatic glycogenesis,[5] lipogenesis,[4,8] and gluconeogenesis from lactate.[5] As glucose tolerance deteriorates and the hepatic compensations become inadequate, lipemia and glycemia are observed. Lastly, deterioration of renal, vascular, and cardiac tissue occurs and the animal dies of a variety of diseases at middle age. The average life span of the male BHE rat is about 600 days. That of normal Wistar or Sprague-Dawley rats is between 1000 to 1200 days. A diet rich in sucrose can hasten the appearance of lipemia and glucose intolerance and further shorten the life span of these rats. Substitution of a highly saturated fat for an unsaturated fat such as corn oil can likewise alter the time frame for the appearance of these genetic traits and alter gluconeogenic rate,[6] mitochondrial activity,[7] and glucose oxidation.[8] Almost all of the work with BHE rats has been done with male rats to avoid the confounding effects of the estrus cycle on the measurements made. It is quite likely that the female BHE rat may have these same characteristics but little documentation exists that assures us that this is so. Nonetheless, given the genetic tendency of the strain to manifest noninsulin dependent diabetes mellitus, and the report of Arnold and Thye[9] that female BHE rats have an abnormal glucose tolerance, we decided to explore the possibility that female rats might be useful in the study of gestational diabetes. In this article we report results of our work to develop such a model.

Material and methods

Two experiments were conducted. The main difference between the studies was the duration of feeding of the special diets. Experiment 1 consisted of a short-term (3 weeks) feeding period that preceded gestation, whereas experiment 2 consisted of a long-term (25 weeks) feeding period that preceded gestation. The short-term study used 175-day-old rats (12 rats per group), whereas the long-term study rats (20 rats per group) were fed the diets from weaning and ranged from 225 to 250 days of age at mating. The animals were housed in a room controlled for temperature (21 ± 1° C), humidity (45% to 50%), and light (lights on 6 A.M. to 6 P.M.). Food and water were always available. The animals were bred in double-wide hanging wire mesh cages and were removed to single cages after mating. The papers that underlined the cages were

examined daily. Mating was determined by the appearanace of a vaginal plug on the papers under the mating cage. Male rats were removed from the cage as soon as the plug appeared. This was considered day 0 of the gestation period. Rapid weight gain in the first week after mating was considered to be evidence of conception. After glucose tolerance tests (GTTs) were conducted at 19 days' gestation, dams were placed in plastic shoe box cages with treated pine shavings as bedding. The dams were monitored until parturition was complete. At parturition, the litter was counted and weighed. The dams were weighed weekly and their food intakes were determined.

Before mating, at 19 days' gestation, and at 10 days post partum, glucose tolerance was determined. Day 19 was selected as representative of late gestation. The GTT consisted of a 6-hour fast that preceded a load dose of glucose (25% glucose solution, 1 ml/100 gm body weight) administered by gavage. Tail blood samples were drawn before glucose administration and at 30, 90, and 150 minutes later. The incremental area or the difference over time between the fasting glucose level and that after the glucose pulse, was calculated and compared with the use of the Student *t* test.[10] Both serum glucose[11] and insulin[12] levels were determined in the short-term study, whereas only the glucose level was determined in the long-term study. Glucose tolerance was determined at 400 days of age in the long-term study. The ratio of the 0 to 150-minute incremental area of glucose to insulin, the insulinogenic index,[13] was calculated and compared. To assess the relationship between insulin concentration and glucose concentration, the insulin/glucose ratio was calculated (μU/ml insulin divided by mg/dl glucose).[13]

The rats were fed either a 5% or 22% fat diet (Tables I and II). The composition of the 22% fat (high-fat) diet was determined on the basis of the composition of the average American diet[14] in terms of sources of calories from the macronutrients. The saturated/unsaturated fat ratio was replicated, as was the ratio of polysaccharides to disaccharides and monosaccharides. Purified ingredients were used to construct the diet. The low-fat or 5% fat diet was created on the basis of the proximate composition of the stock diet usually fed to our rat colony. The same ingredients and ratios within macronutrients were used as for the high-fat diet.

Table II. Diet composition (kcal/100 kcal)

	5% Fat	*22% Fat*
Lipid	11.7	42.5
Protein	20.8	10.3
Carbohydrate	67.5	47.2

In experiment, 1, the progeny were removed from their dam within 2 hours of birth and were killed by decapitation. Blood was collected and was used for the determination of glucose and insulin levels, and the body was used for the determination of its proximate composition. In study 2, litters were size limited to 4 to 6 pups. Male pups were killed at birth, day 3, and day 10 and were used for the histologic examination of the inguinal fat pads. Whole body cross sections were prepared in accordance with the procedures of Hausman and Richardson.[15] Sliced paraffin sections (7 μm) were stained with periodic acid-Schiff reagent to determine the presence of soluble polysaccharides in cell membrane and were counterstained with Harris hematoxylin to distinguish cellular nuclei. Inguinal adipocytes in periodic acid-Schiff–stained histologic sections were identified and diameters were determined on 50 randomly selected inguinal adipocytes per animal.

Results

Experiment 1. This experiment was conducted to examine the effect of short-term, high-fat feeding on glucose tolerance during gestation and gestation outcome. Several differences in food intake were obesrved: rats fed the high-fat diet ate significantly more than rats fed the low-fat diet (29.3 ± 1.7 versus 24.9 ± 1.0 kcal/100 gm body weight per day) during the initial week on the experimental diets and gradually diminished their intake during the next 2 weeks so that food consumption was similar (25.7 ± 1.5 versus 25.1 ± 1.4 kcal/100 gm body weight per day) in both groups at mating. Food consumption was increased during each week of pregnancy in the low-fat rats and only during the second trimester in the high-fat rats. Significant differences in food intake between the low-fat and high-fat rats were observed during the first and third trimesters ($p < 0.05$). Despite the observed differences in food intake, the body weights of the two dietary groups were not significantly different, nor was body weight gain during gestation affected by diet. Rats fed

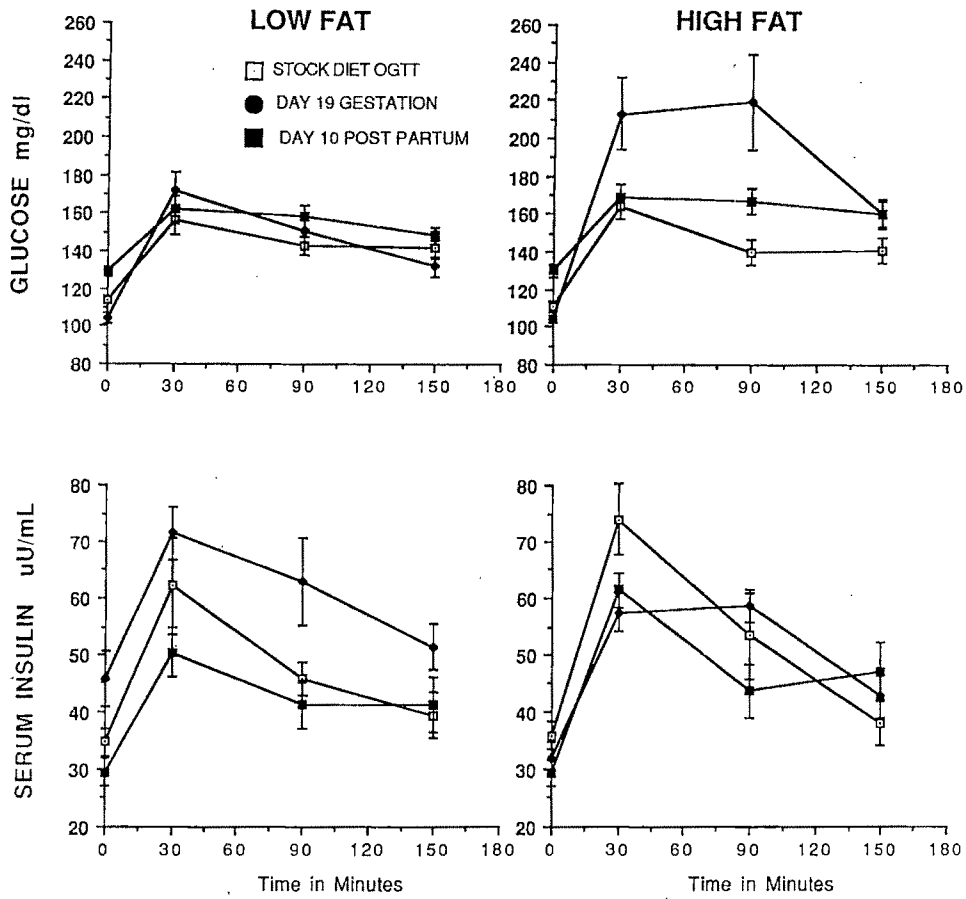

Fig. 1. Effects of short-term low-fat or high-fat feeding on glucose and insulin response to oral glucose load before and after gestation (experiment 1).

the low-fat diet gained 94 gm ± 8.8 gm, whereas rats fed the high-fat diet gained 86.6 gm ± 8 gm. Low-fat dams had 11.4 ± 0.9 pups per litter and high-fat dams had 9.3 ± 0.5 pups per litter.

Basal levels of serum glucose, measured after a 6-hour fast, increased when animals were changed from the stock diet to either of the purified diets (112 mg/dl ± 1.7 mg/dl on stock versus 131.3 mg/dl ± 4.5 mg/dl and 129.6 mg/dl ± 2.9 mg/dl on low-fat and high-fat diets, respectively). Pregnancy in low-fat rats led to a decrease in basal serum glucose levels and an increase in basal serum insulin levels (Fig. 1). This is consistent with the study of Martin et al.[16] that used rats of a normal strain. In the high-fat rats, pregnancy was associated with a decrease in basal serum glucose levels and no change in basal serum insulin levels. Basal serum glucose and insulin levels returned to initial values by day 10 post partum in both low-fat and high-fat rats.

Glucose tolerance was similar in both dietary groups in the nonpregnant state (before breeding and on day 10 post partum) but was increased by pregnancy to a greater extent in the high-fat rats than in the low-fat rats. The 0 to 150-minute mean incremental glucose area (Fig. 2) was increased in the pregnant low-fat rats compared with their nonpregnant counterparts. It is likely that this was a result of the pregnancy-induced reduction in basal serum glucose levels. The mean incremental glucose area was further increased in the pregnant high-fat rats. A significant difference in the 0 to 150-minute mean incremental glucose area was observed between the two dietary groups during pregnancy. This difference indicated a greater degree of glucose intolerance in the high-fat rats. This impairment was only temporary; by day 10 post partum, glucose tolerance in the high-fat rats had improved. The 0 to 150-minute mean incremental glucose area of the postpartum high-fat rats was comparable to that of the postpartum low-fat rats. The insulin response of the pregnant rats to the oral GTT was similar to that in the nonpregnant state regardless of diet (Figs. 1 and 2). The insulinogenic index was similar in the low-fat and high-fat rats before breeding. During pregnancy, the insulinogenic index decreased in the high-fat rats and increased slightly in the low-fat rats. A significant difference in insulinogenic index was observed during

pregnancy between the two dietary groups ($p < 0.05$). During the postpartum period, the insulinogenic index increased in the high-fat rats to a value that was similar to that of the postpartum low-fat rats.

The effects of maternal diet on selected parameters in newborn BHE rat pups is not presented because, despite the observed differences in maternal glucose tolerance, there were no differences in average pup weight, serum glucose and insulin levels, pancreatic soluble protein, pancreatic insulin content, and body composition.

Experiment 2. This experiment was conducted to examine the effect of long-term high or low fat feeding on glucose tolerance during gestation and gestation outcome. Food intakes (approximately 25 kcal/100 gm body weight per day) by both diet groups were similar throughout the experiment.

Rats fed the two diets differed in their body weight gain. Those fed the high-fat diet gained more weight than those fed the low-fat diet. However, most of the difference in weight gain was attributed to four of the 20 rats fed the high-fat diet. These four rats became obese. When this small subset was removed and was treated as a separate group, the diet difference in weight gain was not significant. Weight gain during gestation was not affected by diet. Low-fat dams gained 84.1 gm ± 8.3 gm and high-fat dams gained 97.9 gm ± 9.6 gm during pregnancy. At 400 days of age, rats fed the high-fat diet weighed 400 gm ± 10 gm and those fed the low-fat diet weighed 360 gm ± 10 gm.

At 200 days of age, glucose tolerance was significantly depressed in high-fat rats, as compared with low-fat rats (Fig. 3). Basal levels of serum glucose measured after a 6-hour fast decreased when the rats were pregnant. This is consistent with the reports of an improvement in glucose tolerance with pregnancy in streptozocin diabetic rats.[16] Glucose tolerance was improved in high-fat rats during gestation and at 10 days post partum as compared with tolerance before breeding. At each of the testing times the high-fat rats' glucose tolerance was less than that of the low-fat rats. Their 30-minute post dose blood glucose values were higher and the rate of decline in blood glucose from 30 to 150 minutes was less. These results are in contrast with those of experiment 1 in which glucose tolerance was depressed in rats that were fed the high-fat diet only during gestation.

Compared with the short-term study in which diet had no effect on fertility or pregnancy outcome, the long-term feeding of the high-fat diet significantly affected fertility as well as production (Table III). Fertility (conception and successful completion of pregnancy) was decreased fifty percent in dams that were fed the high-fat diet. Of the 20 rats that were fed the high-fat diet, only half conceived. Of those that conceived, 30%

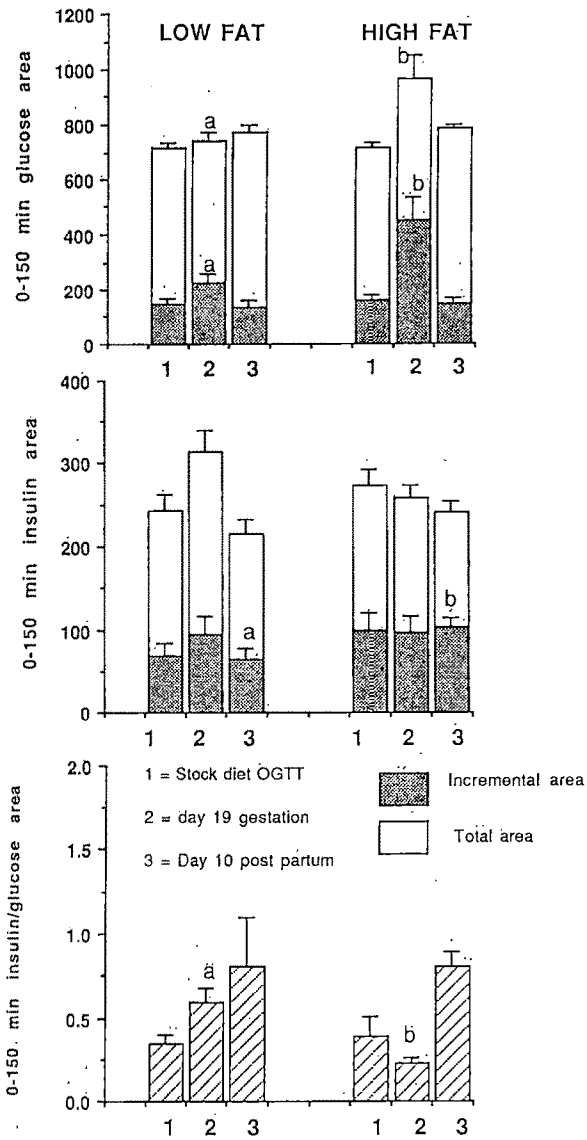

Fig. 2. Effects of short-term low-fat or high-fat feeding on total and mean incremental areas under glucose tolerance curves obtained before, during, and after gestation. Superscripts *(a, b)* indicate significant differences because of diet.

did not rear young. The pups of these dams either died at birth or shortly thereafter. Of the rats that were fed the low-fat diet, 35% did not conceive and 15% of these did not rear young. Diet had no effect on litter size, litter weight, or average pup weight. As previously mentioned, four of the rats that were fed the high-fat diet became obese. Only one of these conceived. However, all of her pups died at birth. Of the pups born to the dams fed the high-fat diet, 25% died at birth. Of the pups born to the low-fat dams, 17% died at birth. The usual mortality rate in our stock diet–fed rat colony is <10%.

Diet also affected gestation time, which in turn probably affected neonatal mortality. The average gestation

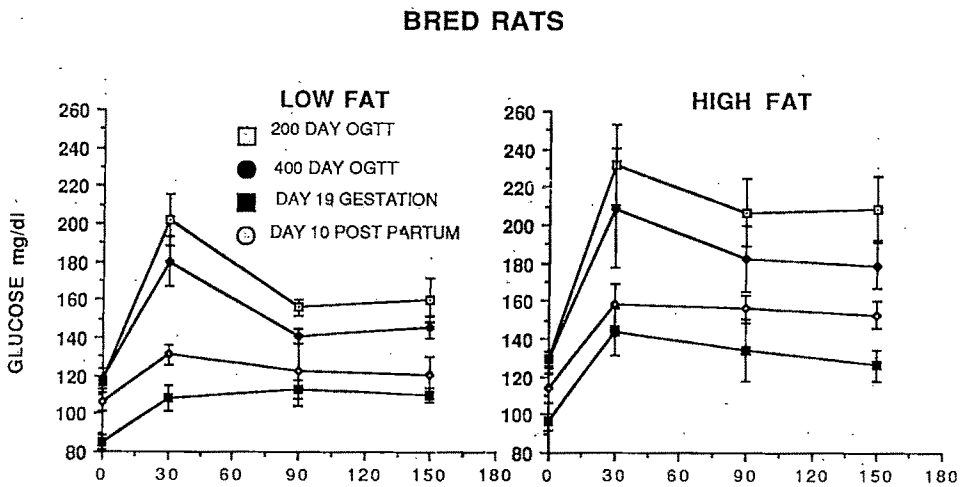

Fig. 3. Effects of long-term high-fat feeding and gestation on glucose tolerance of female BHE rats.

Table III. Effect of maternal diet on fertility, litter size, litter weight, average body weight, and lactation (experiment 2)

	Diet	
	5% Fat	*22% Fat*
Number of dams initially	20	20
Number of dams that conceived	13	10
Number of dams that bore young	13	10
Number of dams that reared pups	11	7
Percentage of dams that gave birth to live young	55% (11:20)	35% (3:20)
Percentage of dams that did not lactate	15% (2:13)	30% (3:10)
Average length of gestation (days)	22.7	22.9
Average litter size	6.2 ± 1.1	7.0 ± 1.1
Average litter weight (gm)	37.8 ± 6.3	41.2 ± 5.7
Average pup weight (gm)	6.3 ± 0.2	6.0 ± 0.2
Total number pups	80	65
Numbers of pups that died during neonatal period	14	16
Percentage of pups that died	17% (14:80)	25% (16 65)

time was 22.7 days for the low-fat dams 22.9 days for the high-fat dams. Five of the low-fat group had a 23-day gestation and one had a 25-day gestation. Seven of the high-fat group had a 23-day gestation and one had a 24-day gestation. The normal gestation period of stock-fed dams in our BHE colony is 21 days. All of the pups of the dams with 24- and 25-day gestation periods died. One of the pups of a high-fat dam with a 23-day gestation was malformed and died. The high-fat dam with the 24-day gestation had only two pups, which weighed 8 gm and 7.9 gm, respectively. Both pups died at birth. Both low-fat and high-fat dams had small litters. The average litter size for the low-fat dams was six, whereas the average litter size for the high-fat dams was seven. The usual litter size of our colony BHE rats is 12 with pup weights ranging from 5 gm to 6 gm. Because we wanted to follow up these dams to 400 days of age we did not look for evidence of resorptions. Hence, we can only assume that fetal death and resorption had occurred, which could account, in part, for the small litter sizes. As in the short-term study, the surviving pups were normal in all respects. We did not observe macrosomia in the surviving young. Birth weight and size of inguinal pad adipocytes of offspring were not affected by dam's diet; however, there were differences in growth. By 10 days of age, low-fat pups weighed significantly more (27.4 gm ± 0.79 gm versus 21.1 gm ± 1.7 gm) than the high-fat pups. This increase in body weight was not accompanied by an increase in fat cell size.

Comment

The purpose of this work was to develop a rat model that might be useful for the study of gestational diabetes as it occurs in human beings. It has long been recognized that noninsulin dependent diabetes mellitus has a strong genetic component and so we used a rat strain with a genetically determined predisposition for noninsulin dependent diabetes mellitus. In human beings, it is also recognized that women who show evidence of gestational glucose intolerance may later have noninsulin dependent diabetes mellitus. Gestational diabetes has been considered an early warning signal of the latent disease. Before our use of the special diets we conducted several preliminary studies* of the pregnant

*PhD dissertation. Dorothy B. Hausman. Studies on the development of a rat model for human gestational diabetes. Athens, Georgia: University of Georgia, 1985 (C. D. Berdanier, dissertation director).

BHE and normal or streptozocin-treated Sprague-Dawley rats. These studies revealed that the BHE rats that were fed a stock diet that consisted of a variety of natural ingredients (mostly cereals and grains) did not show evidence of impaired glucose tolerance during gestation. Neither age nor parity influenced this finding. Streptozocin treatment did elicit impaired glucose tolerance but this impairment was not solely associated with gestation. Therefore we concluded that streptozocin diabetic rats were not good models for gestational diabetes nor were the BHE rats that were fed the stock diet.

With the realization that male BHE rats require special purified diets for the expression of their noninsulin dependent diabetes mellitus phenotype, we then decided to study the BHE female rat within this context. Inasmuch as the stock diet is not a replicate of the human diet, we decided to compose a diet that resembled (in terms of its proximate composition) a diet consumed by the average American.

This was a serendipitous choice because female BHE rats manifested many of the characteristics of the human woman who has glucose intolerance during pregnancy. In the first study we showed that the BHE rats that were fed the high-fat diet did indeed show evidence of glucose intolerance during pregnancy but not before or after pregnancy. We did not observe the macrosomia or other perinatal problems in the pups that we expected if our rats truly modeled human beings. Perhaps the species differences in the level of maturity of the progeny at birth might be an important consideration. Rat pups, compared with human infants, are relatively immature. They are blind, hairless, and have very primative stubs for limbs. The human infant, in contrast, usually has all of its faculties and has relatively well developed arms, hands, legs, and feet.

In the second study, the dams used were reared on the low- or high-fat diets and then were bred. It is of interest that we observed several additional breeding problems that might have been related to the phenotypic expression of the noninsulin dependent diabetes mellitus genotype and that might be analogous to the human condition. These problems consisted of decreased fertility, presumed increased fetal death, increased neonatal death, decreased ability to lactate with the consequence of pup death because we elected not to hand feed these pups, and prolonged gestation times. Those dams that had prolonged gestation times gave birth to fewer live pups and these pups were larger and more mature in terms of their development than normal pups. Whether this prolonged gestation time is analogous to the human woman with gestational diabetes is unknown because human beings with this condition usually are closely supervised. Their glucose intolerance is treated and the pregnancy is brought to term as soon as is deemed medically desirable to achieve a successful pregnancy outcome. Failure to bring the pregnancy to term could result in sudden fetal death or abnormalities, primarily dystocia, related to the abnormal size of the infant. In this study we did not treat the glucose intolerance nor did we terminate the pregnancies at the end of the normal 21-day gestation period. Whether the large size of the pups we observed was a result of the prolonged gestation or gestational diabetes per se is not known.

Several investigators have studied the rat as a possible animal model for gestational diabetes.[16-18] Some of the features of diabetes have been elicited but none, so far, have developed a model that is normoglycemic before and after gestation but hyperglycemic during gestation. For example, Neufeld and Corbo[17] used the streptozocin-treated rat and found that maternal and fetal glucose levels were significantly elevated as was in vitro hepatic insulin receptor binding. They also found that insulin degradation was faster in the progeny of the diabetic dam than in the progeny of the control dam. They did not report on the glucose-insulin relationship during either the pre- or postgestation period but one can assume that the streptozocin treatment elicited a long-term glucose intolerance and not just one that occurred during pregnancy. Thus the streptozocin-treated rat is a good model for insulin-dependent pregnant human beings but not for the gestationally diabetic woman. Catlin et al.[18] induced fetal hyperinsulinemia by the injection of fetuses with 2 units of insulin 2 days before birth. They produced pups that were 12% heavier at birth and that showed evidence of a greater growth velocity than their saline solution–treated litter mates. Although the liver and muscle of the insulin-treated pups contained more lipid than the tissues of the saline solution–treated pups, rates of fatty acid synthesis were not different. They produced large pups but did not measure cell size so we do not know if these pups were macrosomic. Perhaps the next iteration of the present work might focus on the development of a procedure that will elicit not only the glucose intolerance during late pregnancy but also macrosomia in living pups. Inasmuch as high-sucrose feeding has been shown to increase insulin production and release, perhaps raising the sucrose level in the high-fat diet would have this effect. Further work is needed to more fully develop the BHE rat fed a 22% fat diet as a model for human gestational diabetes.

Addendum

Since this manuscript was submitted, we have learned that peripheral fat cell glucose transport, insulin binding, and receptor affinity are normal in these rats and the genetic error resulting in noninsulin dependent diabetes mellitus is only in the liver.

Infusion of the prostaglandin synthetase inhibitor 4-aminoantipyrine at a rate of 20 mg/min via the fetal tarsal vein during normothermic conditions (ambient temperatures = 24° C) significantly decreased the concentrations of prostaglandins E_2 and $F_{2\alpha}$ in maternal and fetal arterial plasma and in uterine and umbilical vein plasma. The infusion was associated with a small but significant rise in fetal temperature and a fall in fetal arterial pH. Respiratory alkalosis developed in fetuses during hyperthermia by raising the ambient temperature to 43° C for 8 hours. In contrast, infusion of 4-aminoantipyrine during hyperthermia produced fetal metabolic acidosis as indicated by a fall in fetal pH and an increase in $Paco_2$, even though the ewe remained hypocapnic. Four of the 10 fetuses died during or shortly after the 4-aminoantipyrine infusion during hyperthermia. These results indicate that uteroplacental prostaglandin synthesis is essential to allow the fetus to adapt to an increase in body temperature and suggests that prostaglandin synthetase inhibitors should be used with caution during pregnancy. (Am J Obstet Gynecol 1989;161:241-7.)

Key words: Prostaglandin, 4-aminoantipyrine, hyperthermia, fetal death

Prostaglandins (PGs) are present in both the maternal and fetal circulations from early pregnancy in sheep and increase during gestation, particularly before and during labor.[1] Much of this PG is probably produced by the placenta, since the concentrations of PGE_2 and $PGF_{2\alpha}$ are higher in uterine and umbilical vein plasma than in maternal and fetal arterial plasma, respectively.[2]

The role of PGs for fetal growth and development is not understood, but PGE_2 has both cardiovascular and endocrine effects in the fetus,[3, 4] and both PGE_2 and $PGF_{2\alpha}$ are responsible in part for the nonlabor uterine contractions present throughout much of pregnancy in sheep.[5] PG concentrations are increased after surgery in growth-retarded fetal lambs[6] and during hypoglycemia in fetal lambs and foals.[7-9] It has been suggested that PGE_2 may act as a circulating hormone in the fetal lamb, and because of its actions on the adrenal cortex and lung, it may act to accelerate organ maturation and fetal viability.[6, 8] PGs may also regulate uteroplacental and umbilical blood flows,[10] although this has recently been questioned.[11]

We have shown that there is an increase in the concentrations of PGE_2 and $PGF_{2\alpha}$ in uterine vein and umbilical vein plasma when pregnant sheep are subjected to hyperthermia.[12] Prolonged hyperthermia during pregnancy may result in fetoplacental growth retardation,[13] but it is unclear if the increased synthesis and release of PGs contribute to this growth deficit or are part of the compensatory changes by which the fetus adapts to the increased tissue temperatures. In this study we show that inhibition of PG synthesis during hyperthermia leads to severe fetal acidosis, sometimes resulting in fetal death, which suggests that the increase in PG synthesis is important for fetal adaptation to increased temperatures that may occur naturally from time to time in pregnancy.

Material and methods

Surgical procedures. Ten pregnant Border Leicester/Merino ewes were used. Surgery was carried out at 118 to 122 days' gestation, and at least 7 days elapsed before the fetuses were studied.

Anesthesia was induced by intravenous administration of 5% sodium thiopentone and maintained, after intubation, with 1% to 2% halothane in oxygen and nitrous oxide (50:50 v/v). With the use of sterile procedures, a paramedial incision was made in the maternal abdominal wall, thereby exposing the pregnant uterus. A polyvinyl catheter was placed in the uterine vein (inner diameter 0.86 mm; outer diameter 1.50

mm). Through a small hysterotomy, a fetal hindlimb was exposed, and similar polyvinyl catheters were inserted 5 to 6 cm into the tarsal vein and femoral artery. A polyvinyl catheter was also inserted in the umbilical vein via a cotyledonary tributary vein. A temperature probe (two temperature-sensitive diodes in series encased in silicone and calibrated in a water bath for temperatures between 35° and 45° C) was placed deep in the groin of the fetus and secured between the muscles close to the femoral artery. A temperature probe was also attached to the greater omentum in the abdomen of the ewe. A maternal arterial catheter was inserted in the carotid artery via an incision in the neck of the ewe.

In three sheep nonocclusive electromagnetic flow probes (Micron Instruments Ltd., California) were placed around the main uterine artery.

Experimental protocol. On the day of an experiment, each fetus received two infusions of 4-aminoantipyrine (10 gm/dl, 0.2 ml/min) via the tarsal vein, beginning at approximately 8:00 AM and 4:00 PM; each infusion lasted for 2½ hours. Blood samples (3 ml) were taken from the fetal femoral artery, maternal carotid artery, and uterine and umbilical veins at 60 and 5 minutes before and at 90, 110, 130, and 150 minutes after the start of each infusion and 1 and 2 hours after completion of the second infusion. Samples were collected from the four vessels within 1 minute of each other and kept on ice until they were divided into aliquots.

At the completion of the first 4-aminoantipyrine infusion, the room temperature was raised to 43° ± 1° C from approximately 10:00 AM until 6:00 PM. The second 4-aminoantipyrine infusion started when the ewe had been subjected to 5½ hours of hyperthermia. Fetal and maternal temperatures were recorded at regular intervals through this time.

From each sample of blood, 0.5 ml was used to measure pH, blood gases, and oxygen saturation by means of Radiometer ABL30 and OSM3 equipment; packed cell volume was also determined from this aliquot. The remaining blood was divided into (1) a 1.5 ml sample placed in a polypropylene tube containing lithium heparin and (2) a 1 ml sample placed in a polypropylene tube containing aspirin (0.05 mg) and ethylenediaminetetraacetic acid (0.7 mg). After centrifugation at 2500 rpm for 10 minutes at 4° C, the plasma from the lithium heparin tubes was stored at −20° C until used for determination of 4-aminoantipyrine, glucose, and $PGF_{2\alpha}$. The plasma from the aspirin/ethylenediamine tetraacetic acid samples was mixed with an equal volume of a solution containing methoxyamine hydrochloride (final concentration, 0.12 mol/L in 1.0 mol/L sodium acetate bufer, pH 5.6) and left overnight at room temperature before storage at −20° C. This plasma was used for assay of PGE_2.

Assays and recordings. 4-Aminoantipyrine was assayed in 0.1 ml of plasma by means of the colorimetric assay of Mendelsohn and Levin[14] as described by Huckabee.[15] Glucose was measured enzymatically by the method of Trinder.[16] $PGF_{2\alpha}$ was measured by direct radioimmunoassay with antiserum raised in rabbits (kindly given by Dr. M. Mitchell). The sensitivity of the assay, which was defined as the concentration of $PGF_{2\alpha}$ corresponding to the bound count that was significantly ($p < 0.05$) less than that of the zero concentration, was 0.18 nmol/L. The intraassay coefficient of variation was <10%, and interassay coefficients of variation were

11.6% at 2.66 nmol/L and 15.6% at 1.65 nmol/L. Cross-reactivities with other PGs and metabolites were <0.4% except for thromboxane B_2 (6.21%), 6-keto-$PGF_{1\alpha}$ (5.4%), 13,14-dihydro $PGF_{2\alpha}$ (4.2%), and PGD_2 (3%).

Plasma PGE_2 was measured as PGE_2-methyloxime by means of an antiserum raised in goats against methyloximated PGE_2.[8, 17] Sensitivity of the assay was 0.05 nmol/L. The intraassay coefficient of variation was <10%, and interassay coefficients of variation were 10% at 14.58 nmol/L and 15.6% at 43.24 nmol/L.

Fetal and maternal temperatures were recorded when blood samples were collected. Phasic uterine artery blood flow was recorded from the electromagnetic probe; calibrations were made in vitro as described by the manufacturers (Micron Instruments Ltd.).

Calculations. Blood gases were corrected to the prevailing temperature with the use of the equations published by Lotgering et al.[18] Uterine and umbilical blood flows were calculated from the formulas described by Meschia et al.[19] The average concentration difference of 4-aminoantipyrine between uterine vein and maternal artery and umbilical vein and fetal femoral artery determined from the four pairs of samples was used to derive an average value for uterine and umbilical blood flows, respectively. 4-Aminoantipyrine was assumed to distribute between plasma and red blood cells as for antipyrine, and blood concentrations were calculated from plasma water concentrations as described by Meschia et al.[19] Loss of 4-aminoantipyrine from the fetus other than by placental transfer was assumed to be negligible.

Statistical analyses. Data are presented as mean ± standard error of the mean. Comparison between groups and within treatments have been made by means of analysis of variance. Analysis of uteroplacental blood flows was carried out by unpaired t tests.

Results

Temperature, blood gases, and plasma glucose. During the infusion of 4-aminoantipyrine into the fetus under normothermic (ambient temperature = 24° C) conditions, a small but significant rise in fetal body temperature was noted, (+0.3° C, $p < 0.05$; Table I). This increase was associated with a significant decrease in fetal arterial pH (−0.032, $p < 0.05$) and an increase in arterial P_{CO_2} (+6.8 mm Hg, $p < 0.001$), indicating that 4-aminoantipyrine infusion resulted in fetal acidemia with a respiratory component (Table I). There was no significant change in maternal body temperatures or blood gases during 4-aminoantipyrine infusion under normothermic conditions.

After 5½ hours of hyperthermia (ambient temperature = 43° C), there was a significant rise in maternal body temperature (+2.2° C, $p < 0.001$; Table II). Fetal body temperature was also significantly elevated (+2.2, $p < 0.001$) so that the fetomaternal temperature gradient was maintained. The rise in temperature resulted in maternal and fetal respiratory alkalosis (Tables II and I, respectively). There was no significant change in arterial P_{O_2} of the fetus during hyperthermia.

The infusion of 4-aminoantipyrine into the fetus during hyperthermia did not further change maternal or fetal body temperature or maternal arterial pH, P_{CO_2}, P_{O_2}, or oxygen saturation (Table II). However, infusion of 4-aminoantipyrine during hyperthermia significantly reduced fetal arterial pH and P_{O_2} (Table I). The acidemia was followed by fetal death either during, or within 5 hours of the end of the hyperthermia in four of the 11 trials. No fetal death occurred after two prolonged (3-hour) 4-aminoantipyrine infusions in the sheep kept at normal ambient temperatures (data not shown).

Plasma glucose concentrations in both maternal and fetal arterial circulations were unchanged by the in-

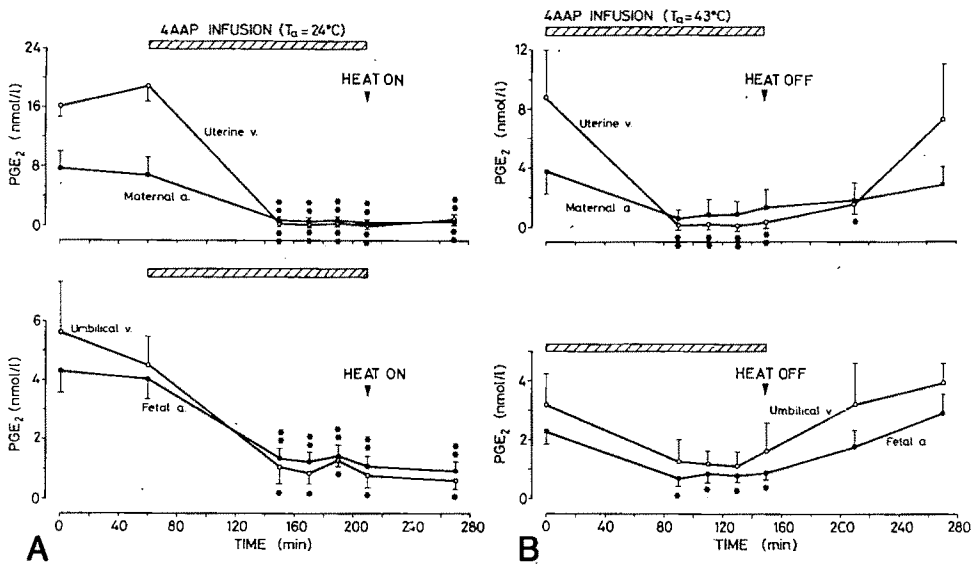

Fig. 1. Concentrations of PGE_2 in fetal and maternal circulations before and during infusion of 4-aminoantipyrine at 20 mg/min into fetal tarsal vein at ambient temperatures (T_a) of **(A)** 24° C and **(B)** 43° C. Second infusion of 4-aminoantipyrine was started 5½ hours after onset of heating.

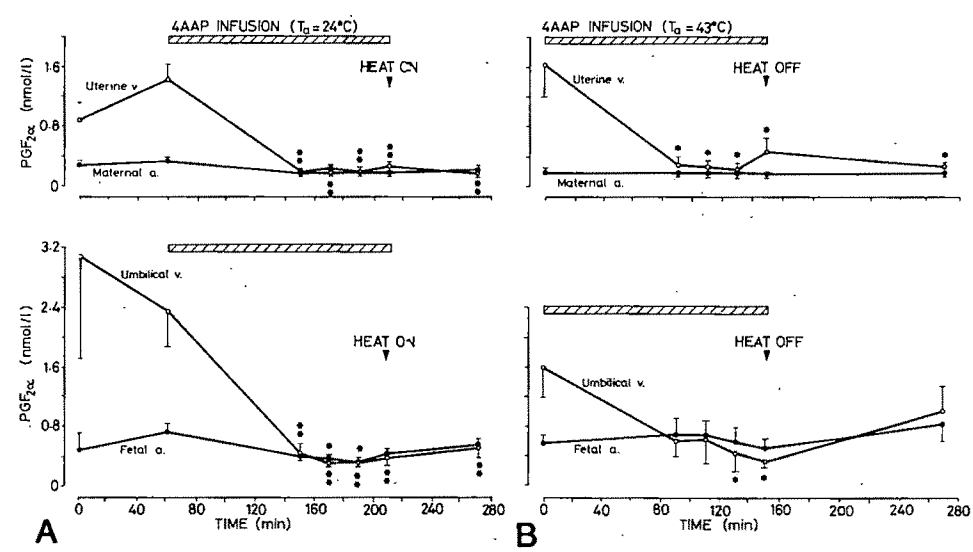

Fig. 2. Concentrations of $PGF_{2\alpha}$ in fetal and maternal circulations before and during infusion of 4-aminoantipyrine at 20 mg/min into fetal tarsal vein at ambient temperatures (T_a) of **(A)** 24° C and **(B)** 43° C. fusion of 4-aminoantipyrine at normothermic temperatures (Tables I and II). During hyperthermia, the infusion of 4-aminoantipyrine into the fetus resulted in a significant increase in fetal plasma glucose concentrations (+0.29 mmol/L, $p < 0.05$) with no change in maternal plasma glucose concentrations.

PGE_2 and $PGF_{2\alpha}$ concentrations. After 90 minutes of 4-aminoantipyrine infusion into the fetus under normothermic or hyperthermic conditions, there was a significant reduction in the plasma concentrations of PGE_2 and $PGF_{2\alpha}$ in both the maternal and fetal circulations (Figs. 1 and 2). The inhibition of PG synthesis persisted for as long as 2 hours after the infusion. Under normothermic conditions, infusion of 4-aminoantipyrine caused a significant reduction in PGE_2 in all four vessels and in $PGF_{2\alpha}$ in the uterine and umbilical veins and fetal artery (Fig. 1). After 5½ hours of hyperthermia and immediately before the start of the second 4-aminoantipyrine infusion, plasma PGE_2 and $PGF_{2\alpha}$ concentrations had recovered to control levels. During

hyperthermia, infusion of 4-aminoantipyrine again caused a significant decrease in the concentrations of PGE_2 and $PGF_{2\alpha}$ in uterine vein and fetal femoral artery plasma and of $PGF_{2\alpha}$ concentrations in the umbilical vein plasma (Figs. 1 and 2). PGE_2 concentrations in maternal artery and umbilical vein plasma did not decrease during this infusion in hyperthermia (in contrast to the significant decrease observed under normothermic conditions), but it should be noted that plasma concentrations in these vessels remained lower than the initial control values obtained at the beginning of the experiment. This suggests that the first infusion of 4-aminoantipyrine may have had a prolonged inhibitory effect on PG synthesis, which was still present after 5½ hours of hyperthermia.

Uterine and umbilical blood flows. The infusion of 4-aminoantipyrine into the fetal tarsal vein at normothermic temperatures (n = 3) did not change the blood flow measured in one main uterine artery by means of nonocclusive electromagnetic flow meters (Fig. 3).

The mean uterine blood flow, which was calculated from the steady-state concentration difference of 4-aminoantipyrine between uterine vein and maternal arterial plasma, increased from 1364 ± 110 ml/min before hyperthermia to 1820 ± 147 ml/min after 8 hours of hyperthermia (n = 8; $p < 0.05$, Table III). Mean umbilical blood flow, which was calculated from the steady-state concentrations of 4-aminoantipyrine in umbilical vein and fetal arterial plasma, was 822 ± 124 ml/min during normothermia (Table III). In experiments in which the fetus survived, mean umbilical blood flow was reduced, but this was not significant. In two of these experiments, umbilical blood flow was significantly lower than the control value during hyperthermia, and fetal pH fell significantly during hyperthermia (−0.168 and −0.315 pH units).

Comment

These results show that inhibition of PG synthesis with 4-aminoantipyrine during hyperthermia leads to a compromise of fetal condition, as shown by the development of fetal acidemia and fetal death. The acidemia is particularly significant when it is considered that, under this level of heat stress, fetal lambs usually develop a respiratory alkalosis as a result of maternal hyperventilation.[20-22] It is unclear if the fetal hyperglycemia observed during hyperthermia was caused by catecholamine release because of the acidemia[23] or may have been the result of diminished insulin responsive-

ness caused by the reduction in plasma PGs.[24] The reduction in umbilical blood flow in some experiments seems to be related to the metabolic changes, since reduction of PG synthesis alone does not alter placental blood flow.[11] Concurrent fetal acidemia and decreased umbilical blood flow have been noted in other experimental situations (e.g., during maternal hyperglycemia[24, 25]), but the mechanisms contributing to these changes have not been delineated. However, it is clear that the presence of 4-aminoantipyrine and the reduction of plasma PGs under hyperthermic conditions lead to a disturbance of fetal metabolism, metabolic acidemia, and decreased umbilical blood.

The fact that such extreme acidosis occurred during hyperthermia when PG synthesis was suppressed and that four of the 10 fetuses died indicates that the increase in plasma PG concentrations that normally occurs during hyperthermia[12] has an important role in enabling the fetus to adjust to the stress of hyperthermia. The cardiovascular and endocrine effects of PGE_2 in fetal sheep include the maintenance of a dilated ductus arteriosus,[26] release of cortisol,[4] and augmentation of insulin secretion during hyperglycemia.[24] Although the impact of hyperthermia on fetal metabolism is not fully understood, plasma glucose and cortisol concentrations were not consistently increased when fetal and maternal body temperatures were raised by 1° to 2° C.[12, 20] Also, the increase in fetal arterial pH appears to be almost entirely caused by the decrease in arterial P_{CO_2} and does not obscure a change in fetal metabolism that otherwise tends to decrease arterial pH. This study suggests that PGs play an important role in allowing fetal and maternal body temperatures to rise without causing a pathologic disturbance of fetal metabolism.

Morishima et al.[27] noted that in anesthetized pregnant baboons hyperthermia resulted in increased uterine activity. We have observed that this also occurs in unanesthetized pregnant sheep (unpublished observations), and this may be caused by the increase in both PGE_2 and $PGF_{2\alpha}$ concentrations during hyperthermia. The complete cessation of uterine activity found by El Badry et al.[28] and us[29] to occur during 4-aminoantipyrine infusion confirms that PGs are important for nonlabor uterine activity. It is unclear if this preterm activity has important effects on fetal homeostasis or development. Harding and Poore[30] have shown that nonlabor contractions are associated with a decrease in uterine blood flow. During hyperthermia when there would be a tendency for vascular dilatation, inhibition of PG synthesis may allow greater dilatation to occur within the myometrium, perhaps resulting in a relative shift in uterine blood flow away from the cotyledons. We have shown that hyperthermia is normally associated with the maintenance or increase in total uterine blood flow (this study and that of Andrianakis et al.[22]), but the partitioning of the flow between myometrium and placenta is not known.

Uteroplacental blood flow, as measured in this study by the steady-state method with 4-aminoantipyrine infusion, was significantly increased during hyperthermia. Although this could be considered a result of the inhibition of PG synthesis, we have also observed that uterine blood flow is increased during hyperthermia when there is an increase in maternal and fetal plasma PG concentrations.[22] These observations, together with those obtained with electromagnetic flow meters (this study and Cashner et al.[11]), question the importance of PGs in the regulation of uterine blood flow in vivo as reported by others.[10]

There was no significant change in mean umbilical blood flow during hyperthermia as measured by the steady-state technique in this study. However, there was a clear decrease in umbilical blood flow in the two experiments in which the arterial pH decreased. In four other trials the fetuses became severely acidotic and died soon after the start of the 4-aminoantipyrine infusion during heat. That these changes are the result of the interaction of 4-aminoantipyrine infusion is shown by the observation that heat alone results in fetal alkalosis without fetal loss.[20-22] Further work is required to determine whether these effects of 4-aminoantipyrine are caused by the inhibition of PG synthesis, resultant fetal metabolic acidemia and hyperglycemia, or other pharmacologic effects of 4-aminoantipyrine.

These observations suggest PG synthetase inhibitors should be used with caution during pregnancy in humans. Although it is apparent that short-term inhibition of PG synthesis does not normally affect fetal condition adversely (although a small fall in fetal arterial pH and rise in temperature were noted), the fetus is no longer able to adapt if a rise in body temperature is imposed at this time. If a pregnant woman uses aspirin or other PG synthetase inhibitors and then experience a rise in body temperature because of one of a number of factors (e.g., exercise, hot environment, or fever), the ability of the fetus to cope with this challenge might be compromised.

We thank Julie Norman for help with the surgery and Lynne Hepburn for typing the manuscript.

Progesterone antagonist lilopristone: A potent abortifacient in the common marmoset

Chander P. Puri, PhD, Rohini K. Patil, BSc, Sanjiv D. Kholkute, PhD, Walter A. G. Elger, MD, and Xavier R. Swamy, BA

Bombay, India, and Berlin, Federal Republic of Germany

The effects of a progesterone antagonist ZK 98.734 (lilopristone) on implantation, early pregnancy, and midpregnancy were studied in the common marmoset, *Callithrix jacchus jacchus*. Treatment (5 mg/day intramuscularly for 3 consecutive days) on day 10 (n = 8) after the midcycle peak in estradiol levels in mated animals induced a premature drop in plasma progesterone levels and shortened the ovarian cycle length. Treatment on day 20 (n = 5) or day 40 (n = 5) induced a drop in progesterone levels and decidual collapse. In three animals treated on day 40, vaginal bleeding was observed within 46 hours of the initiation of treatment. Treatment on day 80 resulted in expulsion of the fetuses with a mean induction abortion interval of 39 hours (range, 20 to 48 hours). The progesterone antagonistic effects of ZK 98.734 could be a result of the decrease in progesterone synthesis by the corpus luteum and/or placenta in addition to the interference with the progesterone binding to its cellular receptors in the target organ. Our study suggests that ZK 98.734 has potential for fertility regulation. Clinical trials for postcoital contraception, induction of menstruation, and early abortifacient effects are warranted. (AM J OBSTET GYNECOL 1989;161:248-53.)

Key words: Progesterone antagonist, lilopristone, abortifacient, progesterone, common marmosets

Progesterone is indispensable for the nidation of fertilized ovum and maintenance of pregnancy. The blocking of progesterone biosynthesis[1-3] or inhibiting its action at the target organ[4, 5] interferes with these physiologic events. Recently three progesterone antagonists (RU 486, mifepristone; ZK 98.299, onapristone, and ZK 98.734, lilopristone) have been identified that compete for hormone binding at the target site and thus prohibit progesterone from eliciting hormonal effects. These compounds are being evaluated as postcoital contraceptive, implantation inhibitor, menstrual inducer, or early abortifacient.

RU 486 is a progesterone antagonist that blocks progesterone synthesis[6, 7] and intercepts progesterone action at the cellular level.[4] In nonpregnant monkeys[8-10] and women[6, 11] it is an effective menstrual inducer. Treatment with RU 486 induces vaginal bleeding in pregnant women in the majority of cases; however, the expulsion of conceptus is often incomplete.[12, 13] Treatment within 10 days of missed periods induces complete abortion in about 80% of the women and the efficacy is further reduced (average, 63%) when the treatment is delayed.[14] In some cases the incidence of vaginal bleeding is heavy and requires emergency curettage.[15] This clinical efficacy is lower than that achieved by prostaglandin analogs.[16] However, when RU 486 is used in combination with prostaglandin analogs, the abortifacient efficacy is increased to 95%.[17, 18]

ZK 98.299 also has high affinity for progesterone receptors in the endometrium of bonnet monkeys[5] and humans.[19] Its administration during the midluteal phase decreases serum progesterone levels and induces menstruation in the bonnet monkeys.[20] Its administration during early pregnancy induces vaginal bleeding in all the animals but the conceptus is expelled only in about 60% of the animals (unpublished observations). In guinea pigs, priming with ZK 98.299 markedly enhances uterine prostaglandin sensitivity.[21] ZK 98.299 has not been clinically evaluated; however, it appears that it may also require a supplementary oxytocic agent for complete abortion, as does RU 486.

Structurally ZK 98.734 more closely resembles RU 486 than ZK 98.299.[22] Its antiglucocorticoid activity is less than the other two compounds.[22] It is a more potent abortifacient than ZK 98.299 or RU 486 in guinea pigs.[21] In the nonpregnant common marmoset, administration of ZK 98.734 during the midluteal phase induces a drop in plasma progesterone levels and shortens the ovarian cycle length.[23] Similarly, its administration during early pregnancy induces resorption. ZK 98.734 also has a high affinity for progesterone receptors.[23] Therefore it is possible that ZK 98.734 would be

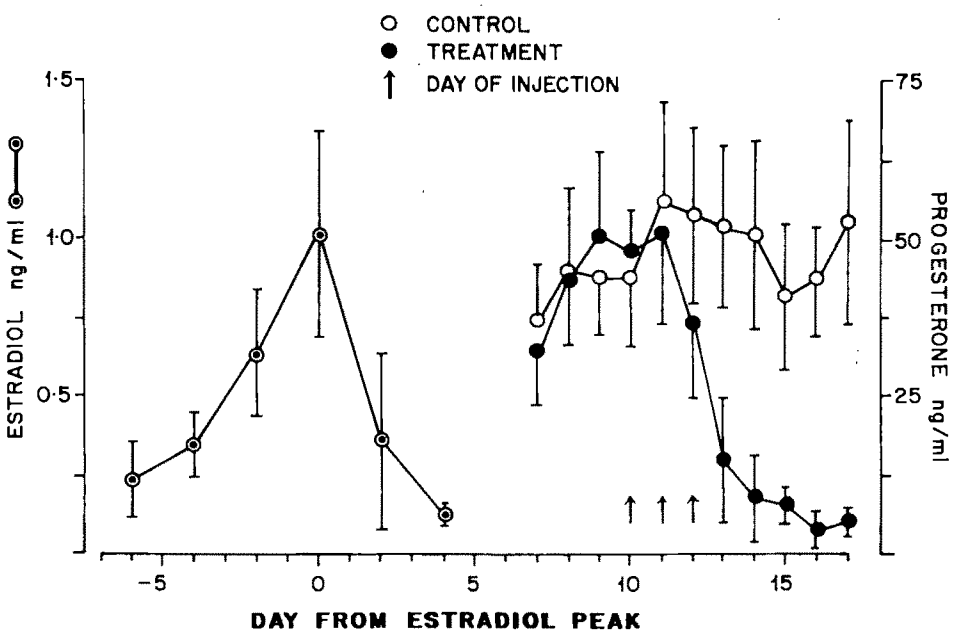

Fig. 1. Effect of ZK 98.734 on luteal phase progesterone levels. Occurrence of midcycle peak in estradiol levels followed by rise in progesterone levels indicates that these animals had ovulated. Progesterone levels (mean ± SD) of five animals in group 1 (control) that became pregnant and eight animals treated with ZK 98.734 (group 2) are shown. Progesterone levels on day 13 were significantly less in group 2 than in group 1 animals.

a more potent abortifacient than the other two compounds.

This study was undertaken to evaluate the efficacy of ZK 98.734 in pregnancy termination in the common marmoset, *Callithrix jacchus jacchus*. ZK 98.734 was administered at four stages of gestation: (1) around the time of implantation, (2) immediately after the ovarian cycle length is extended, which corresponds to missed periods in menstruating nonhuman primate species, (3) on day 40 and, (4) on day 80 after the midcycle peak in estradiol levels (i.e., before and after the luteoplacental shift in progesterone synthesis). Plasma levels of progesterone were estimated to determine the effects of ZK 98.734 on corpus luteum function and on placental progesterone production. The reproductive endocrine profile of gonadal hormones has been extensively studied in this species of nonhuman primates.[24, 25] Like other species of nonhuman primates, ovulation occurs in the common marmoset about 24 hours after the luteinizing hormone surge or 36 hours after the midcycle peak in estradiol levels.[26] Implantation occurs on approximately day 9 to 10 after ovulation.[27] A corpus luteum is necessary for pregnancy sustenance for nearly 48 days after ovulation.[28]

Material and methods

Animals. Common marmosets weighing between 350 and 450 gm were used. The animals were bred at the Primate Facility of the Institute and were housed in rooms maintained at 26° C and controlled photoperiod of 14 hours of light and 10 hours of darkness. They were fed a diet of bread, fresh fruits, vegetables, milk, and water. The details of the management and husbandry have been previously published.[29]

Antiprogestin. ZK 98.734 (11β-(4-dimethylaminophenyl)-17β-hydroxy-17α-(3-hydroxy-prop-1(Z)-enyl-4,9(10)-estradien-3-one) was dissolved in benzyl benzoate at 90° C and was further diluted with castor oil (1:4). A dose of 5 mg in 0.2 ml of the vehicle was injected intramuscularly. Only vehicle was injected in the control group.

Administration of ZK 98.734 or vehicle. ZK 98.734 or vehicle was injected into five groups of animals. The treatment was initiated with respect to the day of midcycle peak in estradiol levels (day 0) as follows: group 1 (n = 8), vehicle from day 10 to day 12; group 2 (n = 8) ZK 98.734 from day 10 to day 12; group 3 (n = 5) ZK 98.734 from day 20 to day 22; group 4 (n = 5) ZK 98.734 from day 40 to day 42, and group 5 (n = 7) ZK 98.734 from day 80 to day 82, unless the animal aborted before the third injection.

Selection of pregnant animals. Common marmosets show postpartum ovulation and in our colony approximately 80% of the animals become pregnant in the first ovarian cycle after delivery.[29] Therefore, marmosets were selected immediately after delivery. The day of parturition was considered day 1. The females were allowed to continue in family groups, with an adult male and their young ones. On postpartum day 15, the males were removed from the cages. Blood samples were col-

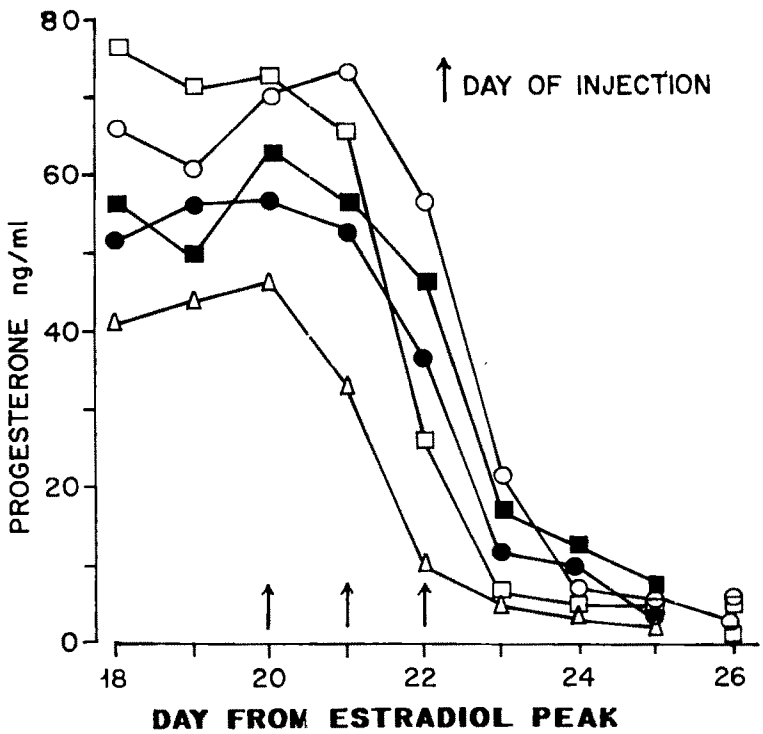

Fig. 2. Effect of ZK 98.734 on pregnancy. Progesterone levels >40 ng/ml on day 20 are indicative of fertile mating. Administration of ZK 98.734 on day 20 to day 22 caused significant decrease in plasma progesterone levels. Pregnancy was terminated in all animals.

lected on alternate days until day 15. Estradiol levels were analyzed immediately to determine the day of midcycle peak in estradiol levels. In groups 1 and 2, in which the treatment was initiated on day 10 after estradiol peak, pregnancy was not confirmed at the time of treatment. Results were analyzed with regard to the basis of hormone levels and the outcome of mating between the control and treatment groups. In the other groups, blood sampling was again started on day 15 and samples collected once daily until day 20. Plasma progesterone levels were immediately estimated and the animals in which progesterone levels on day 20 were >40 ng/ml were considered pregnant.[29] In our colony, marmosets have an ovarian cycle length of 26.6 ± 2.4 days (mean ± SD, n = 14), the midcycle peak in estradiol levels occurs on day 9.2 ± 0.7, and the luteal phase is of 17.4 ± 1.3 days. The pregnant animals were distributed in three groups (groups 3 to 5).

Collection of blood samples. Blood samples (0.3 ml) were collected from the femoral vein once daily for 2 days before and 7 days after the treatment was initiated. Plasma was separated and kept frozen below −20° C until further processed.

Estimation of hormone levels. Plasma levels of estradiol and progesterone were analyzed by specific radioimmunoassay methods. The reagents were provided by the World Health Organization under the Programme of Matched Assay Reagents for the Radioimmunoassay of Hormones in Reproductive Physiology.[30] Estradiol levels were measured with an antiserum raised against estradiol-3CMO-bovine serum albumin (1:210,000) and 2,4,6,7-^{3}H-estradiol (99 Ci/mmol). Mouse monoclonal antibody raised against progesterone-3-CMO-BSA (1:210,000) and 1,2,6,7-^{3}H-progesterone (89 Ci/mmol) were used for progesterone assay. Serum aliquots of 50 μl and 10 μl in duplicate were used for the estimation of estradiol and progesterone levels, respectively. The sensitivities of the assay methods were 5 pg/tube (100 pg/ml) for estradiol and 15 pg/tube (1.5 ng/ml) for progesterone. The coefficients of intraassay and interassay variation (n = 13) were 9.5% and 13.4%, respectively, for estradiol and 8.4% and 12.6%, respectively, for progesterone.

Statistical analysis. Radioimmunoassay data were analyzed with a logit-log transformation of the data on an Apple IIe computer. The differences in progesterone levels between control and treated animals were evaluated by Student's t test.

Results

Effect on pregnancy.

Groups 1 and 2. In group 1 (control, n = 8) five animals became pregnant, thereby indicating a pregnancy rate of 62.5%. The pregnancy was confirmed by the rising levels of progesterone beyond day 17 and subsequent increase in uterine size. Administration of vehicle on day 10 to day 12 had no effect on the luteal function and the pregnancy.

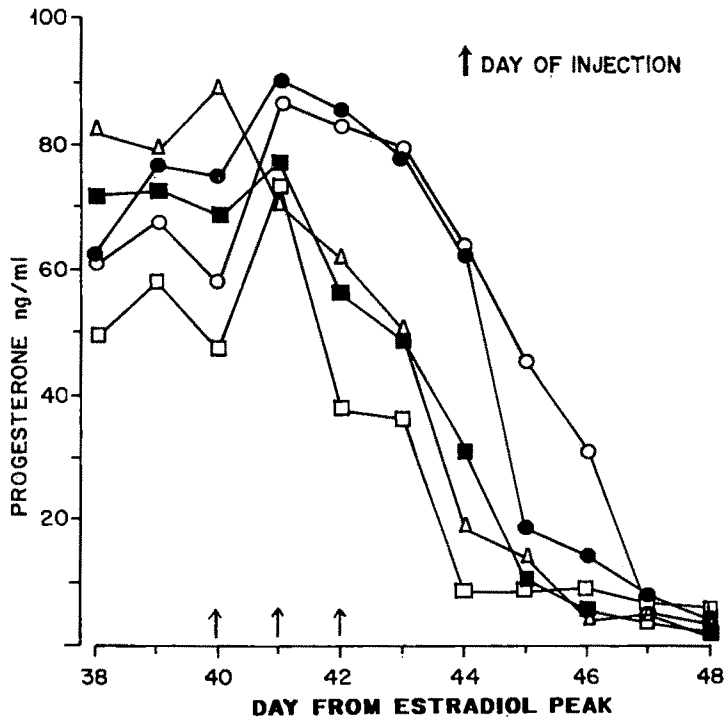

Fig. 3. Administration of ZK 98.734 on day 40 to day 42 caused decrease in plasma progesterone levels. Abdominal palpation was suggestive of resorption of conceptus.

In ZK 98.734-treated animals (group 2), the occurrence of a midcycle peak in estradiol levels followed by a rise in plasma progesterone levels indicated that these animals had ovulated. Administration of ZK 98.734 caused a premature decrease in plasma progesterone levels (Fig. 1). Progesterone levels on day 13 were significantly less ($p < 0.001$) in treated animals compared with the control group. The luteal phase was curtailed and none of these animals continued with pregnancy.

Groups 3 and 4. The administration of ZK 98.734 on day 20 (group 3) or day 40 (group 4) caused a significant decrease in plasma progesterone levels (Figs. 2 and 3). Vaginal bleeding was observed between 32 and 46 hours after the initiation of treatment in three animals treated on day 40. The conceptus was not expelled. Abdominal palpation of the animals in group 4 was suggestive of resorption of conceptus. Pregnancy was terminated in all animals in both the groups.

Group 5. Administration of ZK 98.734 on day 80 induced abortion in all the animals (Table I). Fetuses were expelled between 20 and 48 hours of the initiation of treatment. The mean plasma progesterone levels immediately before the initiation of treatment were 64 ± 11 ng/ml; 72 hours later the levels were 7 ± 3 ng/ml.

Comment

Our study demonstrates that ZK 98.734 is a potent abortifacient in the common marmoset. Its administration at approximately the time of implantation in mated animals inhibited nidation or disrupted the implanted ovum. Because blood samples were collected on alternate days, the day of estradiol peak could be ± 1 day. Therefore it is possible that treatment was initiated just before implantation in some animals. A significant decrease in peripheral plasma progesterone levels and ovarian cycle length were suggestive of pregnancy termination. The posttreatment cycles were ovulatory and of normal duration. Similarly, when the treatment was initiated on day 20 or day 40, a decrease in progesterone levels was observed and the conceptus was resorbed. Conversely, when the treatment was initiated after the luteoplacental shift in progesterone synthesis and when embryonic development was near completion,[31] the fetuses were expelled. Therefore this study suggests that ZK 98.734 has the potential for use as a postcoital method of contraception, as a menstrual inducer, and in the termination of pregnancy.

The abortifacient effects of ZK 98.734 in the common marmoset appear to be similar to that in guinea pigs.[21] In guinea pigs, treatment on postconception day 4 prevents nidation, treatment on day 8 induces decidual collapse and bleeding, and treatment on day 43 induces expulsion of the conceptus. Whereas ZK 98.734 and RU 486 have comparable antinidatory potency, ZK 98.734 induces expulsion more rapidly and at higher rate compared with RU 486.[21]

ZK 98.734 and progesterone are mutually competi-

111	10	Aborted	42	3	1.5

Treatment (5 mg/day) was initiated on day 80.

tive for binding to progesterone receptors in the uterine cytosol of common marmosets[23] and bonnet monkeys.[5] Moreover, ZK 98.734 also exchanges the progesterone-labeled receptor sites in the myometrium of bonnet monkeys.[5] It is therefore possible that the progesterone antagonistic effects of ZK 98.734 could be mediated by interfering with the binding of progesterone to its cellular receptors. However, a significant decrease in plasma progesterone levels observed in this study suggests that the antinidatory or abortifacient effects could also be a result of the reduced progesterone production by the corpora lutea and the placenta. Whether the decrease in progesterone production is the result of direct action of ZK 98.734 on the ovary or is the result of withdrawal of gonadotropin support is not known. In the rat, administration of ZK 98.734 on postcoital day 5 induces structural changes in the corpora lutea that are characteristic of luteolysis; these effects are similar to those observed with RU 486.[32] RU 486 decreases the level of luteal 3β-hydroxysteroid dehydrogenase, which is followed by a decrease in serum progesterone levels in the rat.[33] Similarly, under in vitro conditions RU 486 decreases the activity of 3β-hydroxysteroid dehydrogenase and progesterone production by the human granulosa cells.[7] In the rat ovary, RU 486 binds to progesterone and glucocorticoid receptors,[34] suggesting the possible involvement of progesterone antagonists in progesterone receptor-mediated effects on the ovary. Similarly, the abortifacient effects of ZK 98.734 or structurally related compounds, when administered after the luteoplacental shift in progesterone synthesis, could be a result of a decrease in progestesrone synthesis by the placenta. RU 486 impairs the production of progesterone, human chorionic gonadotropin, and human placental lactogen by the syncytiotrophoblasts in culture.[35] The effects of RU 486 on human chorionic gonadotropin and human placental lactogen are reversed by exogenous progesterone and not with cortisol. RU 486 is rapidly absorbed from the maternal circulation to the fetus through the placenta of rhesus monkeys.[36] Therefore these observations support the possibility of direct action of RU 486 and structurally related compounds on the inhibition of progesterone action in the trophoblast. However, further studies are needed to elucidate the mechanism of action of progesterone antagonists.

Epostane, an inhibitor of progesterone synthesis, is also a potent abortifacient in rhesus monkeys[37] and in humans.[2, 3] Its abortifacient efficacy is quite comparable to that of RU 486.[38] However, the termination of pregnancy with epostane requires repeated administration of the compound for several days and the incidence of side effects such as nausea and vomiting is very common.[2] Moreover, it has not yet been conclusively resolved in primates whether epostane is a selective inhibitor of ovarian and placental progesterone biosynthesis or whether it also affects progesterone production by the adrenal glands, an effect that would not be desirable in view of the role of progesterone as an intermediary in glucocorticoid biosynthesis. Conversely, the use of progesterone receptor-blocking agents would be preferable because of their selective and specific mode of action. Moreover, progesterone receptors are almost exclusively found in reproductive organs and are sensitive to the hormone only at appropriate times.[39] Since ZK 98.734 is a very potent abortifacient in the common marmosets, it can be clinically evaluated as a postcoital method of contraception, "once-a-month pill," or for the termination of early pregnancy.

We thank the World Health Organization for providing reagents for the estimation of steroid hormones. We also thank S. Kadam for assistance with the art work.

Fetal death: Diagnosis and management

To the Editors:

I read the article (Fetal death: Diagnosis and management. AM J OBSTET GYNECOL 1987;157:583-9) by Roy M. Pitkin with great interest and admiration. The purpose of the article was to review the causes and diagnoses of fetal death and to discuss several laboratory tests that offer a much higher yield in the identification of the causes of unexplained stillbirths Our protocol[1] for evaluation of pre- and perinatal death is similar to that proposed by J. C. Carey[2] and others. We use a mnemonic to remember possible causes of unexplained fetal death: MIMAMET (which in Hebrew literally means "from what died?") M = malformations; I = infections; M = muscular; A = autoimmune; M = metabolic; E = endocrine; and T = transfusion.

Despite their rarity, endocrine causes of fetal death (hyperthyroidism and hyperparathyroidism) should be taken in account. The perinatal death rate was 50% in cases of thyrotoxicosis diagnosed in utero[3] and fetal loss has been reported to occur most often late in the pregnancies of untreated cases. Also, overlooked and untreated primary hyperparathyroidism has deleterious effects on both mother and fetus.[4] Many (20%) of the patients with primary hyperparathyroidism were completely without evident symptoms during their pregnancy.[4] For these reasons it appears that calcium, thyroxine, and thyroid-stimulating hormone tests should be routinely performed for every unexplained fetal death.

We also believe that the search for infectious causes of fetal death, such as listeriosis, should be extended to *Ureaplasma, Mycoplasma,* anaerobes, and especially to viral infections (herpes, cytomegalovirus). Benirschke and Robb[5] have demonstrated a high frequency of latent endometrial herpes simplex virus type 2 infection, which produces a true intrauterine herpes simplex virus infection in the embryo or fetus and was an important cause of fetal death.

We continue to take into account muscular causes of fetal death, although reports suggest that myasthenia gravis probably does not increase a pregnant patient's risk of intrauterine death.[6]

Despite these additions, Pitkin's review is very interesting and provides useful and most valuable information for current clinical practice.

Data sought to link adverse pregnancy outcome with maternal serum α-fetoprotein levels in black gravid women

To the Editors:

Macri et al. (Maternal serum α-fetoprotein screening. AM J OBSTET GYNECOL 1987;157:820-2.) document that "the mean of the distribution of maternal serum α-fetoprotein levels in black gravid women is significantly higher than that in other gravid women." He then goes on to state that these women will be subjected to unnecessary anxiety, expense, inconvenience, and potential maternal or fetal harm." In addition, the incidence of open neural tube defects is lower for black women than that for others. Whereas his data should obviously be used for the prediction of open neural tube defects in blacks, it should not be forgotten that elevated maternal serum α-fetoprotein values also predict other pregnancy complications. In the United States, compared with white mothers, black mothers have an increased incidence of pregnancy complications and low birth weight infants. Perhaps this shift in maternal serum α-fetoprotein values for blacks is not normal, but in reality it is related to this increased incidence of adverse pregnancy outcome. Thus it would be helpful if Macri et al. compared their data in black women with regard to birthweight, stillbirth, and spontaneous abortion.

Reply

To the Editors:

As evidenced by our publication in 1978,[1] we have long shared Lenke's interest in the association between elevated maternal serum α-fetoprotein and the higher incidence of complications and low birth weight in pregnancies of black women. This laboratory has developed a large data base on black gravid women. Com-

pletion of the onerous task of securing and analyzing data with regard to perinatal complications including low birth weight will enable us to make known our findings on this association.

Frequency and timing of intravascular intrauterine transfusions reconsidered

To the Editors:

In our country the incidence of severe fetoneonatal hemolytic disease is still rather elevated because of the lack of effective prophylactic planning. In the past radiologically[1,2] and then ultrasonographically[3] guided intrauterine intraperitoneal transfusions helped us to improve neonatal survival in such cases. At present we perform intravascular intrauterine transfusions because the good results of this procedure reported in the literature[4-7] are encouraging. Furthermore, the intravascular route allows us to start treatment before 25 weeks' gestation, to obtain immediate hematologic data, and to determine the amount of blood volume needed to increase fetal hematocrit.

We were surprised to read the extremely good perinatal results reported by Dr. Michael L. Socol et al. (Percutaneous umbilical transfusion in severe rhesus isoimmunization. AM J OBSTET GYNECOL 1987;157: 1369-75). In their study, all hydropic changes in the treated fetuses resolved completely after the transfusions. In our experience, however, the rate of hydropic resolution is much lower, as it is in the other studies published in the literature.[8]

In the past 18 months we have performed a total of 90 intravascular transfusions on 33 patients with severe fetal Rh hemolytic disease. Before the initial transfusion, 16 (48%) of the fetuses had hydrops with ascites, edema, and pericardial effusion. Only four of these (25%) showed hydropic remission after transfusional therapy. A total of 12 (36%) fetuses died in utero. A total of 21 (64%) treated fetuses were born alive; of these, 11 died in the early neonatal period (4 of hydrops fetalis, 1 of cardiac arrest during the exchange transfusion, 2 of cardiac failure, 3 of hyaline membrane disease, and 1 of extreme immaturity).

Anti-D titers have been shown to increase (in some cases from 7.31 μg to 35.2 μg) after intravascular intrauterine transfusions. This antibody rise might result from fetomaternal hemorrhage probably in response to vascular disruption caused by the use of transfusion needles. This forces us to reconsider the frequency of intravascular intrauterine transfusions and the most appropriate time to initiate treatment.

Our results differ from those stated by Dr. Socol et al. Furthermore, we believe that Dr. Socol's findings do not reflect the real danger and irreversibility of most hydropic cases despite intravascular intrauterine transfusions.

Reply

To the Editors:

We appreciate the interest of Drs. Voto and Margulies in our article (Percutaneous umbilical transfusion in severe rhesus isoimmunization: Resolution of fetal hydrops. AM J OBSTET GYNECOL 1987;157:1369-75). We agree fetal hydrops secondary to severe isoimmunization is an ominous sign, particularly if at <26 weeks' gestation. However, we disagree with the statement that hydrops is irreversible in most cases. To the contrary, we believe ultrasonographically guided intravascular transfusions have the capability to considerably improve the prognosis for these pregnancies. A larger series published by Grannum et al. supports our con-

tention.[1] Sixteen of 20 (80%) hydropic fetuses survived and hydrops was completely reversed in 13 of the 16 (81%) fetuses. Consequently, although there are risks associated with fetal blood sampling and intravascular therapy, we continue to believe the ability to gain access to the fetal circulation enhances effective in utero treatment.

Basic reference gambles recommended for utility assessment

To the Editors:

We wish to question Silver and Minogue's analysis (When does a statistical fact become an ethical imperative? AM J OBSTET GYNECOL 1987;157:229-33) with utility scores of elective repeat cesarean section and trial of scar. They asked eight perinatologists to assign utility scores of 0 to 100 (worst = 100) to 11 outcomes that ranged from the minor (the inconvenience of awaiting spontaneous labor and the discomfort of labor) to the major (adverse outcomes of neonatal and maternal death). This is essentially the same as asking the respondents to mark the outcomes on a linear analog scale and is flawed because people always bunch their replies away from the ends of the scale, even when their utilities differ 100-fold, 1000-fold, or more.

The correct method of utility assessment is the basic reference gamble, which in its most widely used form requires subjects to choose between a certainty of an intermediate outcome and a gamble between two extreme outcomes. For example, to measure the relative utility of maternal death and obstetric hysterectomy, subjects would be asked to choose between a certain hysterectomy and a gamble between maternal death and full health. At gambles with high risks of death, say 1 in 10, almost all people would choose hysterectomy, whereas at low risks, say 1 in 10,000, most would choose to risk death. At some risk of death each subject would be unable to decide and that level is defined as the level of indifference.

We are not aware of any surveys of the basic reference gamble between hysterectomy and maternal death but suspect that most North American women (a population not notably averse to hysterectomy) would choose hysterectomy in preference to very low (e.g., much less than 1 in 100) risks of death. Silver and Minogue, however, value hysterctomy at 62 and maternal death at 100. If these values were correct the average woman would choose a 50:50 gamble between full health and death in preference to hysterectomy. Similar ludicrous conclusions are implied by all of the utilities they quote. For example, they value the discomfort of labor as 6 on the same scale, which would imply that women would take a 1 in 20 risk of death to avoid it. We had a similar problem with a recent unpublished survey of patient utilities in relation to surgical management of microinvasive carcinoma of the cervix, in which 30 young women marked their values on a linear analog scale. On a scale with full health and fertility valued 100 and death valued 0, iatrogenic infertility was valued 50. We do not pretend to know what a reasonable utility for infertility should be, but we are fairly certain that 50 is much too low. The problems with linear analog scales and the theoretic and practical aspects of the basic reference gamble are well covered in textbooks of decision analysis.[1]

There is another weakness in their study. They have failed to measure the utilities of elective and emergency cesarean section. These are of crucial importance because, as several authors have argued,[2,3] by avoidance of the risks of emergency operation elective cesarean section may be equally as safe as trial of labor for the mother. In other words, the relatively greater dangers of intrapartum, compared with elective operation, means that the utility of trial of vaginal delivery falls as the chance of success decreases. If this is accepted, the crucial decision is often between risk of fetal death and loss of the satisfaction of normal delivery. At low avoidable risks of fetal death this may be important for some women. Whereas some who value normal delivery relatively low in relation to fetal health will want all possible intervention, others who value the process of natural childbirth relatively high will refuse the same intervention. We are attempting to measure these values, but even with the use of reference gambles it is difficult to obtain internally consistent results. In the meantime, facile acceptance of clearly untenable utilities will bring clinical decision analysis into disrepute. If utilities are used they should be subjected to sensitivity analyses in the same way as probabilities.

Reply

To the Editors:

We would be in agreement with the respondents that our method of assignment of utility scores on a linear scale does not provide the most accurate sensitivity of outcome ranking. Though sensitivity may be reduced by this method, outcome priority (worst to least offensive) is maintained by this method. Inasmuch as priority of outcome is maintained, the various nodes of the decision tree do accurately reflect the originally assigned priorities. Thus the end point comparison of cesarean section versus trial of labor remains valid (i.e., from purely outcome-based analysis, trial of labor provides more benefit and less risk than does repeat cesarean section). Because sensitivity is diminished by our method, the "point spread" between the various nodes of the decision tree may not reflect an appropriate (more sensitive) magnitude of difference.

Certainly, improvement in sensitivity would enhance any decision analysis. But decision analysis, as such, was not our point. In fact, a key objective of the article was to expose a fatal flaw in utility analysis as the *sole* arbiter of ethical decisions. Even with the assumption of a decision analysis method with 100% sensitivity in utility ranking, such ranking would remain highly subjective. Despite the seeming quantitative objectivity of decision analysis, both the ranking and order of magnitude assigned to any outcome are on the basis of personal, subjective preferences. Utility ethics, by making the most good for the most people an absolute, ignores the claims and rights of the few. Translated into quantitative terms, any utility assignment, no matter how sensitive, would have to be on the basis of an average of respondents' scoring. This averaging supports the majority and disenfranchises the minority. Thus the alleged objectivity of utility analysis is actually more a reflection of common opinion than of scientific fact.

Detection of fetal blood

To the Editors:

We read with interest the article, "Ultrasound diagnosis of abruptio placentae with fetomaternal hemorrhage," by Dr. Michael S. Cardwell (Am J Obstet Gynecol 1987;157:358-9). We noted an omission by the author in that he did not consider that 25% of women produce hemoglobin F during pregnancy.[1] This may account for some positive results of Kleihauer-Betke tests. About 1.7% of a population of white Americans had increased numbers of hemoglobin F cells.[2] Moreover, 1.4% of all black Americans have β-thalassemia minor and therefore might have elevated levels of hemoglobin F cells.[3] In a British work 3% of a population was found to have inherited elevated percentages of hemoglobin F cells.[4] The important conclusion is that some patients may have elevated numbers of hemoglobin F cells without fetomaternal hemorrhage. As an alternative to the Kleihauer-Betke test it was recommended to measure α-fetoprotein in maternal blood. This test is more sensitive but it takes more time. We have to point out that maternal serum α-fetoprotein may not be so specific of fetal hemorrhage because it is normally diffused in maternal blood by passage from amniotic fluid. Some authors[5] found that a baseline prehemorrhage sample was necessary; of course, this would be unavailable in maternal trauma patients. Nevertheless, we can overcome these inconveniences in nonurgent cases by repeat blood samples. There are also other tests to detect fetal blood, such as hemoglobin electrophoresis[6] and glycerol lysis time,[7] but most prefer to measure α-fetoprotein in maternal blood as an indicator of fetomaternal bleeding.

Reply

To the Editors:

I wish to thank Drs. Leiberman, Mazor, and Cohen for their interest in my article. They are correct in stating that some patients may have elevated fetal hemoglobin levels associated with β-thalassemia minor or inherited elevated levels of hemoglobin F cells. However, I must point out that elevated α-fetoprotein values are associated with a myriad of conditions, including ventral wall defects, neutral tube defects, and fetal death.[1] Moreover, to reliably detect fetomaternal hemorrhage by α-fetoprotein levels, prehemorrhage and posthemorrhage specimens must be available, which is

usually not the case in patients with suspected abruptio placentae.[2] Most hospital blood banks have around-the-clock facilities to run Kleihauer-Betke tests; α-fetoprotein specimens are usually saved for "batches." Quantitations of the fetomaternal hemorrhage demonstrated by the Kleihauer-Betke stain can be accomplished with the formula derived by Mollison[3]: Fetomaternal hemorrhage (milliliters of fetal red blood cells = 2400 × Fetal red blood cells ÷ Adult red blood cells. Quantitation of the bleeding is not possible with α-fetoprotein values. Although other tests are available to detect fetal blood, the Kleihauer-Betke stain (fetal cell stain) remains the standard test in the United States and is widely used to screen Rh-negative mothers for evaluation and quantitation of the $Rh_o(D)$ immune globulin administration.[4]

Role of ferritin supported in diagnosis of anemias of pregnancy

To the Editors:

I believe the article by Schifman et al. (Schifman RB, Thomasson JE, Evers JM. Red blood cell zinc protoporphyrin testing for iron-deficiency anemia in pregnancy. AM J OBSTET GYNECOL 1987;157:304-7) repeats a mistake that most American investigators have made in the study of anemias of pregnancy. They fail to consider plasma volume expansion and total red blood cell mass (body hematocrit). I predict that the women with the lowest hematocrit in the third trimester actually have the most red blood cells and the biggest infants.[1] Indeed, the bigger the newborn the lower the hematocrit and the higher the incidence of apparent iron deficiency.[2] Studies have reconfirmed that ferritin is indeed the gold standard for diagnosis of iron deficiency anemias of pregnancy and I believe that Schifman's et al. article has only confused the issue.[3]

Reply

To the Editors:

Mild anemia, secondary to increased plasma volume, is a normal physiologic consequence of pregnancy and, as Dr. Goodlin points out, the degree of plasma expansion relates to infant birth weight. Red blood cell mass likewise expands during pregnancy by about 250 ml to 500 ml. This factor, together with fetal growth, places a heavy demand on iron stores, produces a state of negative iron balance, and increases the risk of iron depletion and anemia.[1]

Iron depletion may be absolute (i.e., absent iron stores) or relative, a condition in which reserves are sufficient but are ineffectively used because of increased demands or inflammation. In either case, the ability to expand or maintain red blood cell mass is compromised. Whereas serum ferritin measurement is the gold standard for absolute iron depletion, it does not necessarily identify those with dysfunctional erythropoiesis as a result of excessive or ineffective use of iron.[2]

The red blood cell zinc protoporphyrin test is a functional measure of iron use that detects both absolute and relative iron depletion.[3] In our study, red blood cell zinc protoporphyrin measurements predicted a state of declining red blood cell mass and anemia in third trimester more reliably than did ferritin, presumably because of its sensitivity for the detection of iron depletion erythropoiesis. By the third trimester, most women with elevated red blood cell zinc protoporphyrin values showed hemoglobin values below physiologic anemia levels. If the differences we observed in hemoglobin concentrations were primarily caused by disparate plasma volumes and infant birth weights, rather than by iron depletion erythropoiesis, then the significant correlations we observed between hemoglobin and red blood cell zinc protoporphyrin should also relate to plasma volume differences. However, I am unaware of data that support this supposition, nor would this hypothesis be plausible on the basis of what is known about the cause of elevated red blood cell zinc protoporphyrin concentrations.

Does terbutaline cause uterine atony and increase intraoperative blood loss?

To the Editors:

I read with interest the study of Patriarco et al. (A study on intrauterine fetal resuscitation with terbutaline. AM J OBSTET GYNECOL 1987;157:384-7). My experience with this therapeutic modality would support its usefulness. However, when terbutaline precedes cesarean section within a short period of time (≤15 minutes) I have, on occasion, encountered troublesome uterine atony with a resultant increase in intraoperative blood loss. I have not studied this problem scientifically. Do the authors have any data to suport or refute this clinical impression?

Mark S. Brown, MD
Central Ohio Medical Group
497 E. Town St.
Columbus, OH 43215

Reply

To the Editors:

Dr. Brown had mentioned in his letter to the Editors that occasionally after he gave terbutaline for fetal resuscitation, he had encountered uterine atony with an increase in intraoperative blood loss. We, too, have occasionally encountered uterine atony after terbutaline injection; however, this seems to respond most readily to intravenous oxytocin (Pitocin, Parke Davis). My personal experience is that this additional blood loss is minimal. I have no way to quantitate this blood loss, but it does not appear to be substantially increased. I wonder whether some of this uterine atony may be secondary to the general anesthetics that occasionally are used for emergency cesarean sections, which is usually the case with fetal distress.

Oxytocin may explain neonatal seizures

To the Editors:

As I have tried to point out before,[1] there is an apparent association between the use of oxytocin in labor and neonatal seizures. This perhaps relates both to the changes in newborn sodium levels as well as to the increased incidence of stronger uterine contractions with oxytocin than with natural labor. With regard to the article by Spellacy et al. (Neonatal seizures after cesarean delivery: Higher risk with labor. AM J OBSTET GYNECOL 1987;157:377-9), I presume that the women delivered before labor by cesarean section did not receive oxytocin, whereas a high percentage of women delivered by cesarean section after trial of labor did receive oxytocin. Perhaps the authors have considered this factor in their analysis. If not, I believe oxytocin might be the explanation for the higher incidence of seizures in the laboring group.

Sloane Hospital for Women 1888-1989 a division of The Presbyterian Hospital

29th ANNUAL POSTGRADUATE COURSE IN OBSTETRICS & GYNECOLOGY
October 30 through November 3, 1989

at the New York Academy of Medicine, New York, New York

39 Credit Hours, Category 1, A.M.A.'s Physician's Recognition Award; 37 Cognates, Formal Learning, American College of Obstetricians & Gynecologists; and 37 Elective Hours, American Academy of Family Physicians

FEE: $795 (Residents: $475); includes syllabus, luncheons and refreshments.

Conference Directors: **RALPH J. HESSEKIEL, M.D. & MARVIN H. TERRY GRODY, M.D.**

HAROLD E. FOX, M.D.	ROBERT S. NEUWIRTH, M.D.	JOHN D. THOMPSON, M.D.
RAPHAEL JEWELEWICZ, M.D.	RALPH M. RICHART, M.D.	ILAN E. TIMOR-TRITSCH, M.D.
DANIEL R. MISHELL, JR.; M.D.	MORTIMER G. ROSEN, M.D.	ALAN J. WABREK, M.D.
JAMES H. NELSON, JR., M.D.	DANIEL H. SMITH, M.D.	STERLING B. WILLIAMS, M.D.

This comprehensive program is offered in order to update the practitioner to the current state of the art. We hope to accomplish this through an overview of the major segments of obstetrics & gynecology by a visiting guest faculty of established experts and a select group of specialists and authorities from the faculty of the College of Physicians & Surgeons of Columbia University. The main thrust of the course will examine problems in clinical practice and their resolution through the application of current data, treatment options and surgical techniques. Subspecialties of maternal fetal medicine, oncology and reproductive endocrinology will be covered as they apply to the practice of our specialty by the generalist for whom this course is specifically designed. Lectures on the latest technology, panel discussions with audience participation and evaluation of ethical and medico-legal problems affecting health care delivery should help provide the highest and broadest professional competence in each of the registrants.

Contact: Center for Continuing Education, 630 West 168th Street, N.Y., N.Y. 10032; Telephone: (212) 305-3682.

Medical Genetics Medical Staff Fellowship
The Interinstitute Medical Genetics Program
National Institutes of Health

The Interinstitute Medical Genetics Program of the National Institutes of Health offers fellowships providing a comprehensive clinical and laboratory experience in medical genetics. The fellowships begin July, 1991 and are offered for two years. Applications are invited from individuals of the highest caliber with the M.D. or M.D.-Ph.D. degree who have completed at least two years of post-graduate clinical training and who are seriously interested in pursuing careers in academic medicine and research. Clinical training involves inpatient and outpatient services at the NIH 540-bed research and teaching hospital, which, with collaborating medical facilities, provides a broad exposure to clinical genetics, diagnosis and counseling, cytogenetics, biochemical and cancer genetics, and prenatal diagnosis. Exceptional research opportunities exist in the institutes' multiple laboratories. The program staff includes scientists and physicians of international stature.

As a medical staff fellow you will receive an initial salary of $32,000 with increments of $2,000 per year up to a maximum of $36,000. Moving, travel expenses and Federal health care benefits are available. Interested candidates should submit their *curriculum vitae* to or request further information from.

FACULTY POSITION CHAIRMAN WEST VIRGINIA UNIVERSITY SCHOOL OF MEDICINE

West Virginia University School of Medicine is seeking a CHAIRMAN, DEPARTMENT OF OBSTETRICS AND GYNECOLOGY at Charleston Area Medical Center—the 1000 bed clinical campus of WVU Health Sciences Center. This person will also be Associate Chairman, Department of OB/GYN, WVU School of Medicine. CAMC has a newly opened ultramodern Women and Children's Hospital. CAMC has full resident programs and one third of the WVU medical students in permanent residence for their clinical years at the Charleston Division. Applicants should be accomplished clinicians interested in an academic setting emphasizing teaching and be eligible for a rank of Professor or Associate Professor. Please send CV and letter to Shawn Chillag, M.D., Associate Professor and Chairman, Department of Medicine/CAMC, 3110 MacCorkle Avenue, S.E., Charleston, WV 25304. Closing deadline October 30, 1989. WVU is an affirmative action equal opportunity employer.

Obstetrics and Gynecology Maternal/Fetal Medicine Specialist

The Western Pennsylvania Hospital is seeking a second BC/BE specialist in Maternal/Fetal Medicine to join a rapidly growing division of Maternal/Fetal Medicine in a 550 bed tertiary care center. This is a unique opportunity in that major teaching, clinical and research opportunities are available in this university affiliated center. A fully accredited independent Ob/Gyn Residency training program is in place. This is a level III tertiary care center with a 30 bed neonatal intensive care unit. The Maternal/Fetal Medicine service accepts high risk maternal transports from throughout the tri-state area. A full range of genetic services are also performed at the institution, including chorionic villi sampling, amniocentesis, and genetic counseling. A research building is currently being built, and opportunities are available for both basic and clinical research. This position offers a state of the art practice opportunity, an attractive compensation package, and the chance for one to be creative. Send your CV to:

Mark Caine, M.D.
Director, Maternal/Fetal Medicine
Department of Obstetrics and Gynecology
West Penn Hospital
4800 Friendship Avenue
Pittsburgh, PA 15224

DIRECTOR OF MATERNAL AND FETAL MEDICINE

University of Illinois
College of Medicine at Chicago
and
Michael Reese Hospital and Medical Center

The University of Illinois College of Medicine at Chicago, and Michael Reese Hospital and Medical Center invite applications and nominations for the position of Director of Maternal and Fetal Medicine in the Department of Obstetrics and Gynecology. Academic rank dependent upon qualifications. The Director will lead the Obstetric program of two of Chicago's most important medical institutions, both with a long history of academic excellence and outstanding patient care.

Candidates should be certified in Maternal/Fetal Medicine, have substantial scholarly productivity in the field, and have ability to provide dynamic leadership in administering a comprehensive program of patient care, education, and research in Obstetrics.

Interested individuals should send a curriculum vitae to: Antonio Scommegna, M.D., Professor and Head, Department of Obstetrics and Gynecology, University of Illinois College of Medicine at Chicago, 840 South Wood Street, Chicago, IL 60612. The University of Illinois at Chicago is an affirmative action/equal opportunity employer.

Request for Participation in Maternal Autoimmune Thrombocytopenia Study

We have plans for a treatment study of Maternal Autoimmune Thrombocytopenia. Intravenous Gamma Globulin will be given at 32 + 37 weeks of pregnancy. This will be compared to a similar group receiving no gamma globulin. This study will be done on a randomized basis. History of well documented autoimmune thrombocytopenia prior to present pregnancy will be required for patient entry. Other therapy (steroids, C-section, treatment of infant) will be at local option. We are looking for 10+ centers to participate in such a study. Each center should be able to enroll 5 patients or more for 1 year. If interested in receiving protocol and specifics, please write Dr. William Krivit, Professor of Pediatrics, University of Minnesota Department of Pediatrics, 1252 Ingerson Road, St. Paul, MN 55112.

UNIVERSITY OF MIAMI SCHOOL OF MEDICINE
DEPARTMENT OF OBSTETRICS & GYNECOLOGY

ASSISTANT PROFESSOR OF CLINICAL OBSTETRICS & GYNECOLOGY

Opportunity available for M.D. who is board certified or board eligible in Maternal Fetal Medicine. Special interest in infectious disease is desirable but not required.

Applicant must be licensed in State of Florida, and have sufficient clinical experience to qualify for a full time faculty appointment.

Salary will be commensurate with training and experience. Compensation includes excellent fringe benefit and financial incentive plan.

SPECIAL DELIVERIES. SPECIAL CHALLENGES.

The Southern California Permanente Medical Group invites you to join a unique prepaid health care program. Our multispecialty group practice is a partnership composed of and managed by SCPMG physicians.

Board eligible/certified **PERINATOLOGISTS** are needed for our high-volume obstetric services which handles 3,000-6,000 deliveries per year. Opportunities exist both to join and create high risk services.

There are positions available to practice Perinatology exclusively. Perinatologists who are interested in performing other aspects of obstetrics and gynecology may do so. We also have positions available for Endocrinologists and General Obstetrician-Gynecologists. University affiliation and clinical research are encouraged.

Our compensation is competitive and benefits are outstanding. They include: professional liability, medical and dental coverage, vacation and sick leave, continuing education, life insurance and retirement plans. **After two years full-time employment, physicians are eligible to be considered for partnership.**

For a physician application, please call or write to: William G. McCormick, M.D., Physician Recruitment, Dept. 006, Walnut Center, Pasadena, CA 91188-8013. (714) 829-5365.

Of all the various problems we encounter in obstetrics and gynecology, the most ubiquitous and seemingly ever increasing, is infection. When we're almost convinced we are in control of a problem, resistant strains appear, or a new infectious agent is discovered. To help solve this dilemma, we are offering this comprehensive course in infectious diseases in ob/gyn. Experts in this new subspecialty have been assembled from across the nation to provide current diagnostic and therapeutic information. This is a practical course for the practitioner, and the goal is to send each participant home far better equipped than he or she ever was before to combat the myriad of infectious diseases in the general practice of ob/gyn.

Contact: Center for Continuing Education, 630 West 168th Street, N.Y., N.Y. 10032; Telephone: (212) 305-3682.

BRIDGEPORT HOSPITAL
Bridgeport Connecticut

DEPARTMENT OB-GYN
is seeking a full time

DIRECTOR OF AMBULATORY SERVICES

Bridgeport Hospital, located on Long Island Sound 50 miles from New York, is a 550 bed community hospital affiliated with Yale University.

The hospital has accredited residency training programs in Internal Medicine, Primary Care, Surgery, Pediatrics, Radiology, and Ob-Gyn.

The Ob-Gyn Dept. has 22 BC/BE attendings, including 4 full-time faculty, 2 P.A.'s, and 8 residents.

We are a Level III unit with approx. 3000 deliveries and 8000 clinic visits annually.

Primary responsibilities of this position include supervision and teaching of residents and students in the ambulatory clinics.

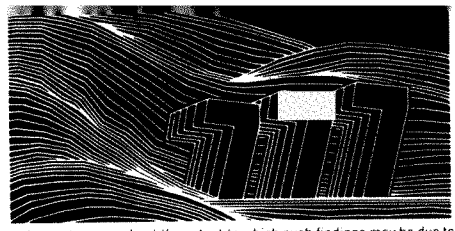
norethindrone/ethinyl estradiol

ach white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet ontains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg nore- hindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

MPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information rovided with the product and therefore should not be used as the basis for prescribing the product. his summary was prepared by deleting from the complete prescribing information certain text, tables nd references. The physician should be thoroughly familiar with the complete prescribing information efore prescribing the product.



NDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

:ONTRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following onditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophle- itis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease.4. Known or suspected arcinoma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-depen- lent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice vith prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contracep- tive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this brief summary is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this brief summary epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contra- ceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and nonusers. The attributable risk does pro- vide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been associated with oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers, especially in those 36 years of age and older among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboem- bolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospital- ization. The risk of thromboembolic disease associated with oral contraceptives is not related to length of use and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four weeks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contracep- tives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non- smokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hyper- tension. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from oral contraceptives. A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estro- gens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. The activity and amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on prepara- tions containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contracep- tives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral contraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attribu- table to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have a significant increase in mortality higher than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. While there are conflicting reports the overall evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on the risk of breast cancer for at least a decade following long term use. Some studies have shown a slightly increased relative risk of developing breast cancer. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of

women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. In spite of many studies of the relationship between oral contraceptive use and breast and cervical cancers, a cause and effect relationship has not been estab- lished. 4. HEPATIC NEOPLASIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contracep- tives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia, papilledema, or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREG- NANCY: RISK OF BIRTH DEFECTS. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recom- mended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secretion and create insulin resist- ance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contracep- tives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As dis- cussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contra- ceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malig- nancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMI- NATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contracep- tives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMO- TIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irreg- ularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased anti-thrombin 3; increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See WARNINGS section. 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlarge- ment. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT: See Patient Package Insert. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section). Thrombophlebitis and venous thrombosis with or without embolism. Arterial throm- boembolism. Pulmonary embolism. Myocardial infarction. Cerebral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reac- tions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes: tenderness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intoler- ance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Ery- thema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal func- tion. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.

ORTHO PHARMACEUTICAL CORPORATION
Raritan, N.J. 08869-0602

Revised 11/88

Low-impact norethindrone

No significant change in mean values for total cholesterol, HDL, and LDL†

21- and 28-day regimens

ORTHO-NOVUM® 777 Tablets

norethindrone/ethinyl estradiol

†Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate.

Please see brief summary of complete Prescribing Information on the preceding page.

Even at midcycle, she wears white with confidence

Only Tri-Norinyl provides a full 1 mg of progestin at the midcycle (days 8–16), when clinical data indicate that breakthrough bleeding and spotting are most likely to occur.[1]

To help control midcycle breakthrough bleeding: make the midcycle the high point of protection.

Extra midcycle progestin to reduce midcycle breakthrough bleeding

9 DAYS
1.0 mg norethindrone

7 DAYS
0.5 mg norethindrone

5 DAYS
0.5 mg norethindrone

21 DAYS *0.035 mg ethinyl estradiol*

TRI-NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

1. Data available from Syntex Laboratories, Inc., document #92363.

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. Before prescribing Tri-Norinyl, please see brief summary of prescribing information on following page.

TRI-NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

TRI-NORINYL® 21-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
TRI-NORINYL® 28-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 7 inert tablets)
BREVICON® 21-Day Tablets (norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
BREVICON® 28-Day Tablets (21 norethindrone 0.5 mg with ethinyl estradiol 0.035 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 35 21-Day Tablets (norethindrone 1 mg with ethinyl estradiol 0.035 mg)
NORINYL® 1 + 35 28-Day Tablets (21 norethindrone 1 mg with ethinyl estradiol 0.035 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 50 21-Day Tablets (norethindrone 1 mg with mestranol 0.05 mg)
NORINYL® 1 + 50 28-Day Tablets (21 norethindrone 1 mg with mestranol 0.05 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 80 21-Day Tablets (norethindrone 1 mg with mestranol 0.08 mg)
NORINYL® 1 + 80 28-Day Tablets (21 norethindrone 1 mg with mestranol 0.08 mg tablets followed by 7 inert tablets)
NORINYL® 2 mg Tablets (norethindrone 2 mg with mestranol 0.1 mg)
NOR-Q.D.® (norethindrone) Tablets 0.35 mg

ORAL CONTRACEPTIVE (O.C.) AGENTS

Indications Prevention of pregnancy. *DOSE-RELATED RISK OF THROMBOEMBOLISM.* Because studies have shown a positive association between OC estrogen dose and risk of thromboembolism, it is prudent to minimize estrogen exposure. Prescribe an OC with the least amount of estrogen compatible with an acceptable pregnancy rate and patient acceptance. Start new users on OCs containing 0.05 mg or less of estrogen.

Contraindications 1. Known or suspected pregnancy (see Warning #5). 2. Thrombophlebitis or thromboembolic disorders. 3. Past history of deep vein thrombophlebitis or thromboembolic disorders. 4. Undiagnosed abnormal genital bleeding. 5. OCs should not be used by women who have or have had any of the following: a. cerebral vascular or coronary artery disease, including myocardial infarction. b. known or suspected carcinoma of the breast. c. known or suspected estrogen dependent neoplasia. d. benign or malignant liver tumor that developed during use of OCs or other estrogen containing products.

WARNINGS: Cigarette smoking increases the risk of serious cardiovascular side effects from OC use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use OCs should be strongly advised not to smoke.

The use of OCs is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, liver tumor, gall bladder disease, visual disturbances, fetal abnormalities, and hypertension. Practitioners prescribing OCs should be familiar with the following information relating to these risks.

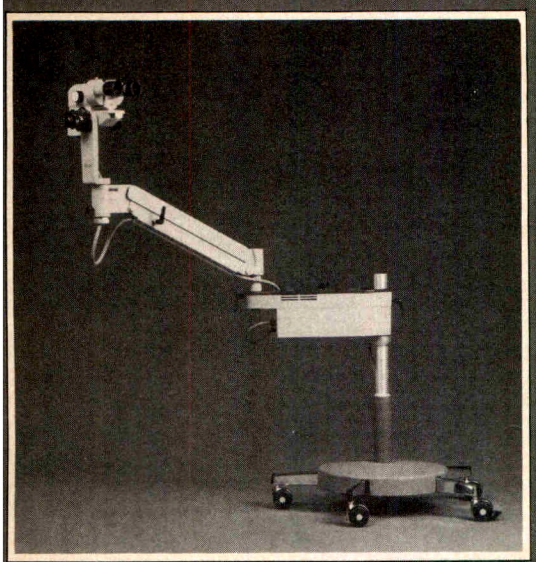
1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with OC use is established. One study demonstrated an increased relative risk for fatal venous thromboembolism and several studies demonstrated it for non-fatal venous thromboembolism. They estimate that OC users are 4-11 times more likely than nonusers to develop these diseases without evident cause. One British study reported an excess death rate of 40% in OC users, most of which resulted from cardiovascular disease. Another British study showed a lower death rate in OC users than controls; an increase in cardiovascular deaths was seen but was not statistically significant. A U.S. prospective study failed to disclose increased mortality rates from cardiovascular disorders, but a subset analyzed as a retrospective, case-control study showed significant increases in venous thromboembolism. CEREBROVASCULAR DISORDERS. Two American studies demonstrated an increased relative risk for stroke not shown in prior British studies. In an American study of cerebrovascular disorders in women with and without predisposing causes, relative risk of hemorrhagic stroke was estimated as 2.0 times greater and thrombotic stroke as 4-9.5 times greater in users than nonusers. A British long-term follow-up study reported in 1976 a highly significant association between OC use and stroke. Another study had suggested an association in 1974, but the number of cases was too small to estimate the risk. Subarachnoid hemorrhage has been shown to be increased by OC use in British and American studies. Smoking alone increases incidence of these accidents; smoking and pill use appear to increase risk more than either alone.

MYOCARDIAL INFARCTION (MI). Increased relative risk of MI associated with OC use has been reported. One British study found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing MI, regardless of OC use. OCs were an additional risk factor. In terms of relative risk, it has been estimated that nonsmoking OC users (smoking is considered a major predisposing condition to MI) are twice as likely to have a fatal MI as nonsmoking nonusers. OC users who are smokers have a 5-fold increased risk of fatal infarction compared to nonsmoking users, and a 10-12-fold increased risk compared to nonsmoking nonusers. The number of cigarettes smoked is important. In determining the importance of these relative risks, baseline rates for various age groups must be considered. (Estimates are based on British vital statistics which show acute MI death rates 2-3 times less than in the U.S. so U.S. death rates could be higher.) Importance of other predisposing conditions in determining relative and absolute risks has not been quantified; other synergistic actions may exist. RISK OF DOSE. Using data from several national adverse reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to estrogen dose in OCs. OCs with 0.1 mg or more of estrogen were associated with a higher risk of thromboembolism than those containing 0.05-0.08 mg but quantity of estrogen may not be the sole factor. This was supported by a U.S. study. A British study found a positive association between dose of progestogen or estrogen and certain thromboembolic conditions. Swedish authorities noted decreased reporting of thromboembolic episodes when higher estrogen preparations were no longer prescribed. Careful epidemiological studies to determine degree of thromboembolic disease risk associated with progestogen-only OCs have not been done. Thromboembolic disease has been reported in women using these products, and they should not be considered free of excess risk. PERSISTENCE OF RISK. Two studies have suggested an increased risk may persist for 6 years after discontinuation of OC use for cerebrovascular disease and 9 years for MI; another study suggested the persistence of risk for subarachnoid hemorrhage. ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES. A large British prospective study estimated mortality rate per 100,000 women per year from circulatory system diseases for OC users and nonusers according to age, smoking habits, and duration of use. The overall annual excess death rate for OC users was estimated to be 20/100,000 (ages 15-34 – 5/100,000; ages 35-44 – 33/100,000; ages 45-49 – 140/100,000). Risk is concentrated in long-term users and in smokers, and may persist after OC discontinuation. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all occurred in women 35 or older. An update provided the following rates: ages 15-34 – 1/6700 for nonsmokers and 1/2000 for smokers; ages 45 and over – 1/2500 for nonsmokers and 1/500 for smokers. Risk appeared to increase with parity, but not with duration of use. Until more women under 35 with continuous use for 5 or more years are available, it is not possible to assess relative risk for this age group. Data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. Estimates include combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease for OCs) plus risk attributable to pregnancy or abortion if the method fails (which varies with the effectiveness of the contraceptive method). The study concluded that mortality associated with all contraceptive methods is below that of childbirth, except for OCs in women over 40 who smoke. (Rates given for pill only/smokers for each age are for smokers as a class. For "heavy" smokers (more than 15 cigarettes a day), the rates would be about double; for "light" smokers (less than 15), about half.) The lowest mortality is with the condom or diaphragm backed up by early abortion. The study also concluded that OC users who smoke, especially over 30, have greater mortality risk than OC users who do not smoke.

Risk of thromboembolic and thrombotic disease associated with OCs increases with age after 30 and for MI is further increased by hypertension, hyperlipidemias, obesity, diabetes, or history of preeclamptic toxemia, and especially by smoking. The following chart gives a gross estimate of risk of death from circulatory disorders associated with OC use.

SMOKING HABITS AND OTHER PREDISPOSING CONDITIONS – RISK ASSOCIATED WITH USE OF OCs

Age	Below 30	30-39	40 +
Heavy smokers	C	B	A
Light smokers	D	C	B
Nonsmokers (no predisposing conditions)	D	C,D	C
Nonsmokers (other predisposing conditions)	C	C,B	B,A



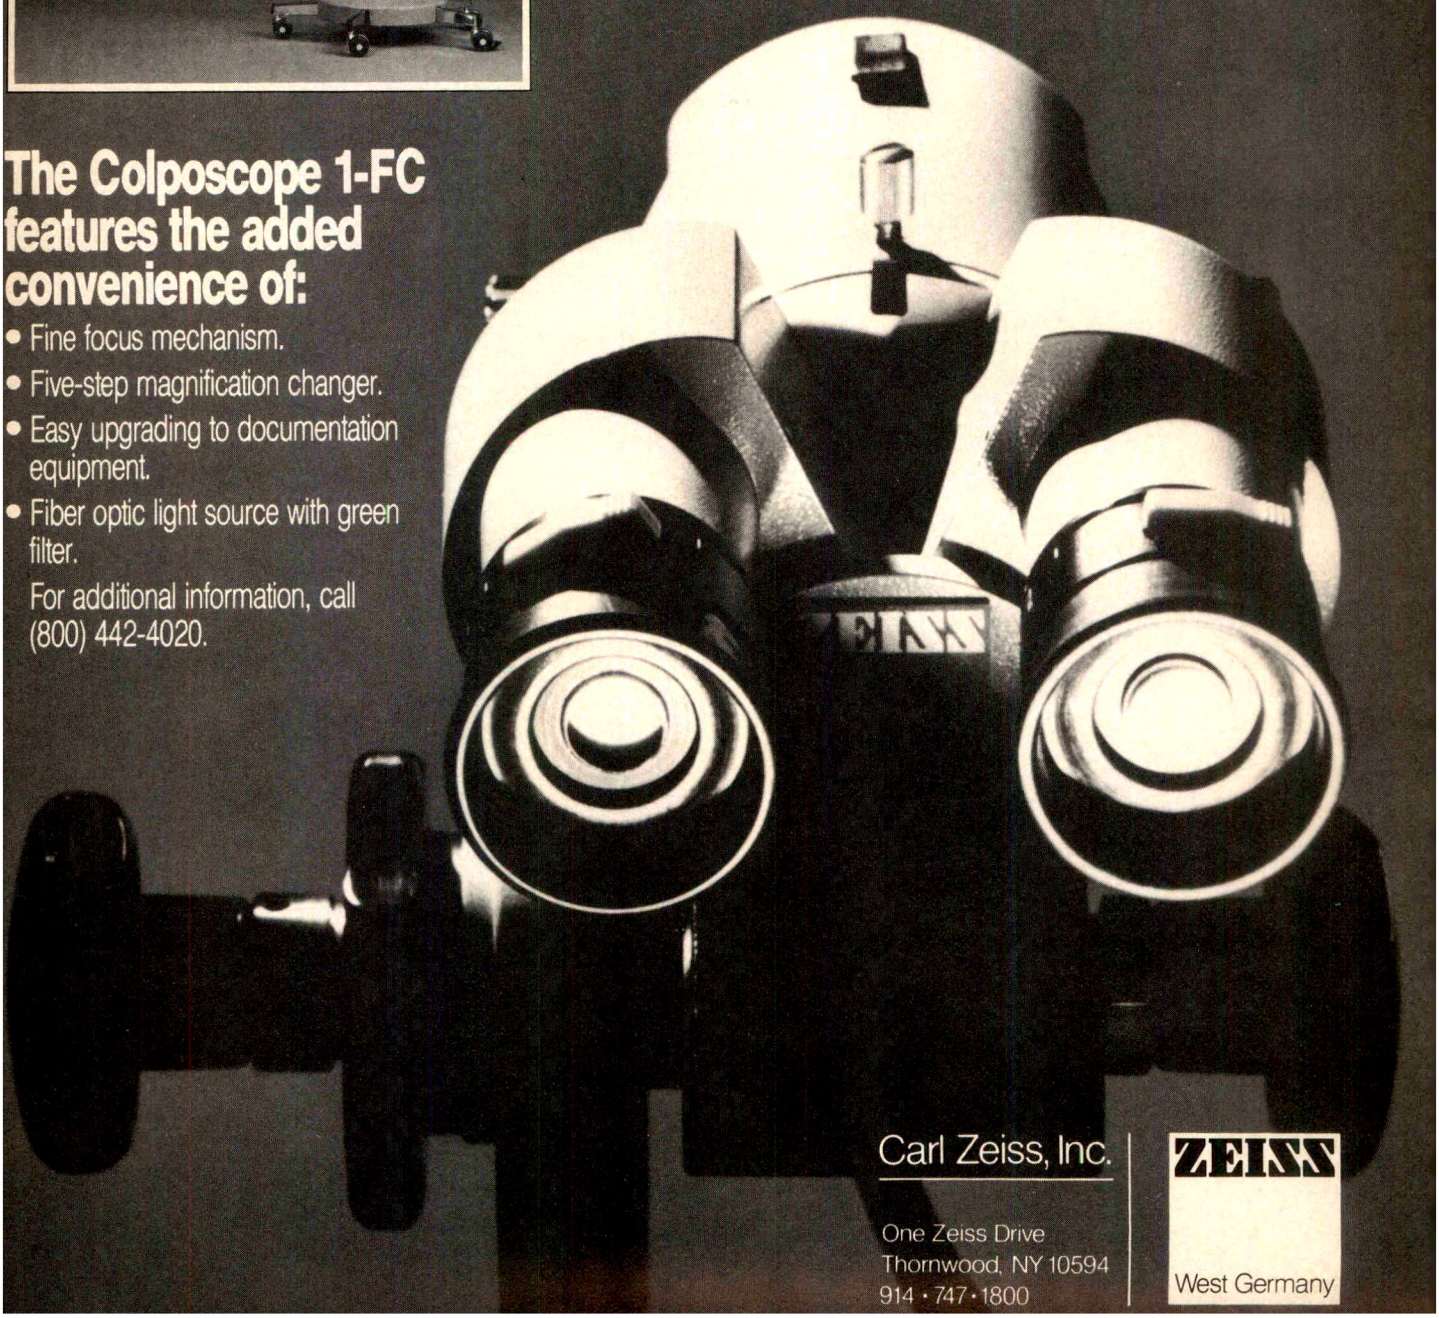
A – Use associated with very high risk.
B – Use associated with high risk.
C – Use associated with moderate risk.
D – Use associated with low risk.

Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, discontinue OC immediately. A 4-6 fold increased risk of post-surgery thromboembolic complications has been reported in OC users. If feasible, discontinue OCs at least 4 weeks before surgery associated with increased risk of thromboembolism or prolonged immobilization. Before resuming OC after major surgery or bedrest, balance risks of post-surgery thromboembolic complications with contraceptive needs. Data suggest varicose veins substantially increase risk of superficial venous thrombosis of the leg, the risk depending on the severity of the varicosities. 2. *Ocular Lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OC use. Discontinue OC if there is unexplained, sudden, or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions, and institute appropriate diagnostic and therapeutic measures. 3. *Carcinoma:* Long-term continuous administration of natural or synthetic estrogen in certain animals increases certain tumors, benign or malignant, such as breast, cervix, vagina, uterus, ovary, pituitary and liver. Certain synthetic progestogens, none currently in OCs, increase the incidence of mammary nodules, benign and malignant, in dogs. Several retrospective case-control studies reported an increased relative risk (31-13.9 times) associating endometrial carcinoma with the prolonged use of estrogens in postmenopausal women. One publication reported the first 30 cases submitted to the registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the adenocarcinomas found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding when OCs were first given, polycystic ovaries), nearly all occurred in women who had used sequential OCs, which are no longer marketed. No statistical association has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs, although individual cases have been reported. Studies have shown no increased risk of breast cancer to OC or estrogen users. One study found no overall increased risk of breast cancer in OC users but a greater risk was suggested for OC users with documented benign breast disease and for long-term (2-4 years) users. Another study found a history of breast cancer among grandmothers or aunts was significantly more frequent among breast cancer patients who had used an OC continuously for one or more years than among nonusers with breast cancer. One other study indicated an increasing risk of breast cancer in women taking menopausal estrogens, which increased with duration of follow-up. One author suggests that extended (over 6 years) OC use prior to first full term pregnancy was associated with a significant relative risk of breast cancer, and other studies suggested an increased risk of breast cancer with long-term OC use before age 25. A reduced occurrence of benign breast tumors in OC users has been well documented. One study reported malignant melanoma more frequently in OC users than controls and suggests an increased incidence of urinary tract and thyroid cancers. A prospective study of women with cervical dysplasia found an increase in severity and conversion to cancer *in situ* in OC users compared to nonusers. This became statistically significant after 3-4 years of use. Nonreversal of dysplasia within the first 6 months of pill use was suggested to predict progression after prolonged exposure. One study disclosed an increased risk of cancer of the cervix (largely carcinoma *in situ*) in OC users under 40, particularly those who had used OCs over 4 years. Two other studies suggested an increasing incidence of cervical neoplasms with longer duration of OC use. There have been other reports of microglandular hyperplasia of the cervix in OC users. One study reported an association between OC use and endocervical adenocarcinoma. In summary, there is no confirmed evidence from human studies of increased risk of cancer associated with OCs. Close clinical surveillance of all OC users is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, take appropriate diagnostic measures to rule out malignancy. Monitor OC users with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms with particular care. (See also Warnings, 4. *Liver Tumors.*) 4. *Liver Tumors:* Sudden severe abdominal pain or shock may be due to rupture and hemorrhage of a liver tumor. There have been reports associating benign or malignant liver tumors with short-term and long-term OC use. One study reported use of OCs with high hormonal potency and age over 30 may further increase risk of hepatocellular adenoma. Two studies relate risk with duration of use, risk being much greater after 4 or more years of use. Long-term OC users have an estimated annual incidence of hepatocellular adenoma of 3-4/100,000. Although an uncommon lesion, it should be considered in women presenting with an "acute abdomen". The tumor may cause serious or fatal hemorrhage. Patients with liver tumors have demonstrated variable clinical features which may make preoperative diagnosis difficult. Some cases presented because of right upper quadrant masses, while most had signs and symptoms of acute intraperitoneal hemorrhage. Routine radiological and laboratory studies may not be helpful. Liver scans may show a focal defect. Hepatic arteriography may be useful in diagnosing primary liver neoplasm. Cases of hepatocellular carcinoma have been reported in long-term users of OCs.[see also] An epidemiological study suggested a 4-fold increase in relative risk for hepatocellular carcinoma in OC users for 8 years or more, which increased to 7 in women with markers of hepatitis B. A second study suggested a risk of about 20 for use in excess of 8 years. 5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring:* Use of female sex hormones – estrogenic and progestational agents – during early pregnancy may seriously damage the offspring. Females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1/1000 exposures or less. Although there is no evidence that OCs further enhance the risk of developing this type of malignancy, such OC users should be monitored with particular care. A high percentage of women exposed to diethylstilbestrol (30-90%) have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are a precursor of vaginal malignancy. Male children so exposed may develop urogenital tract abnormalities. Although similar data are not available on other estrogens, it cannot be presumed that they would not induce similar changes. Increased risk of congenital anomalies, including heart and limb defects, has been reported following use of sex hormones, including OCs, in pregnancy. One case-control study estimated a 4.7-fold increased relative risk of limb-reduction defects in infants exposed *in utero* to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some exposures involved only a few days of treatment. Data suggest risk of limb-reduction defects in exposed fetuses is somewhat less than 1/1000 live births. In a large prospective study, cardiovascular defects in children born to women who received female hormones, including OCs, during early pregnancy occurred at 18.2/1000 births, compared to 7.8/1000 for children not so exposed *in utero*. These results are statistically significant. A Welsh study found a statistically significant excess of neural tube defects among offspring of prior OC users (within 3 months) than among controls. The incidence of twin births may be increased for women who conceive shortly after discontinuing OC use. In the past, female sex hormones were used during pregnancy in an attempt to treat threatened or habitual abortion. There is evidence that estrogens are ineffective, and there is no evidence from well controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. If the patient has not adhered to the prescribed schedule, consider possible pregnancy at the first missed period (or 45 days from the last menstrual period if progestogen-only OCs are used) and discontinue OC use until pregnancy has been ruled out. For any patient who has missed two consecutive periods, rule out pregnancy before continuing the OC. If pregnancy is confirmed, tell the patient about potential risks to the fetus and discuss advisability of continuing the pregnancy. Women who discontinue OCs to become pregnant should use an alternate form of contraception for a period of time before attempting to conceive. A 3-month period is supported by a study suggesting increased frequency of neural tube defects in women impregnated during the first 3 months after cessation of OC use. Do not use progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding as a pregnancy test. 6. *Gall Bladder Disease:* Studies report increased risk of gall bladder disease in OC or estrogen users. In one study, an increased risk appeared after 2 years of use and doubled after 4-5 years. In another study, an increased risk was apparent between 6 and 12 months. 7. *Carbohydrate and Lipid Metabolic Effects:* Because a decrease in glucose tolerance has been observed in a significant percentage of patients on OCs, prediabetic and diabetic OC users should be carefully observed. An increase in triglycerides and total phospholipids has been observed in OC users, but its clinical significance is unknown. 8. *Elevated Blood Pressure:* An increase in blood pressure has been reported with OC use. Hypertension may occur within a few months of beginning OCs. In the first year of use, incidence of hypertension may be no higher in OC users than in nonusers. Incidence in users increases with exposure and in the fifth year of use is 2.5-3 times that in the first year. Age is strongly correlated with hypertension in OC users. Women with a history of elevated blood pressure (hypertension), preexisting renal disease, history of toxemia or elevated blood pressure during pregnancy, familial tendency to hypertension or its consequences, or history of excessive weight gain or fluid retention during the menstrual cycle may be more likely to develop elevated blood pressure when given OCs and should be monitored closely. Even though elevated blood pressure may remain within the "normal" range, closely watch elevations, particularly for women with other risk factors for cardiovascular disease or stroke. High blood pressure may or may not persist after OC discontinuation. 9. *Headache:* Discontinue OC and evaluate the cause of onset or exacerbation of migraine or development of a new pattern of headache which is recurrent, persistent, or severe. 10. *Bleeding Irregularities:* Breakthrough bleeding, spotting, and missed menses often make users discontinue OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, consider nonfunctional causes. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, use adequate diagnostic measures to rule out pregnancy or malignancy. If pathology has been excluded, time or another formulation may solve the problem. While potentially useful in minimizing menstrual irregularity, change to an OC with a higher estrogen content only if necessary since this may increase the risk of thromboembolic disease. Women with a history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may tend to remain anovulatory or to become amenorrheic after OC discontinuation. Women with these preexisting problems should be advised of this and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may occur in women without previous irregularities. A higher incidence of galactorrhea and of pituitary tumors (e.g., adenomas) has been associated with amenorrhea in former users compared with nonusers. One study reported a 16-fold increased incidence of pituitary prolactin-secreting tumors among patients with postpill amenorrhea when galactorrhea was present. 11. *Infertility:* There is evidence of impairment of fertility in women discontinuing OCs in comparison with other contraceptive methods, which appears to be independent of duration of use. While impairment diminishes with time, there is an appreciable difference in the results in nulliparous women for OC and other groups 30 months after discontinuation of birth control. For parous women the difference is not apparent 30 months after cessation of contraception. One study suggests that the incidence of *Chlamydia trachomatis* infection, the leading cause of nongonococcal PID, is increased by OCs. 12. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in OC failure. In progestogen-only OC failures, the ratio of ectopic to intrauterine pregnancies is higher than in nonusers, since the drugs are more effective in preventing intrauterine than ectopic pregnancies. 13. *Breast Feeding:* OCs in the postpartum period may interfere with lactation by decreasing quantity and quality of breast milk. A small fraction of OC hormonal agents has been identified in milk of mothers receiving OCs. Effects, if any, on the breast-fed child have not been determined. If feasible, defer OC use until the infant has been weaned. **Precautions** *GENERAL* 1. Take a complete medical and family history before starting OCs. Pretreatment and periodic physical exams should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant lab tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may enlarge. 3. Observe patients with a history of psychic depression and discontinue OCs if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the OC and use an alternate method of contraception to determine whether the symptom is drug related. 4. OCs may cause some fluid retention. Prescribe with caution, and only with careful monitoring, in patients with conditions that might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma or cardiac, hepatic or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while using OCs. Discontinue OC if jaundice develops. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism that may result in a relative pyridoxine deficiency. The clinical significance is unknown. 8. Serum folate levels may be depressed by OC use. Since the pregnant woman is predisposed to folate deficiency and incidence of folate deficiency increases with increasing gestation, if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and related complications. 9. Advise the pathologist of OC use when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing OCs. For example: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnaneciol excretion. e. Reduced response to metyrapone test. f. Increased phospholipids and triglycerides. g. Temporarily decreased glucose tolerance. 11. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist and temporary or permanent cessation of wear considered. DRUG INTERACTIONS. OCs may be less effective and there may be increased breakthrough bleeding from interactions with rifampin, isoniazid, ampicillin, tetracycline, neomycin, penicillin V, chloramphenicol, sulfonamides, nitrofurantoin, barbiturates, phenytoin, primidone, analgesics, tranquilizers, antimigraine preparations, antihistamines, and griseofulvin. OCs may alter effectiveness of such other drugs as oral anticoagulants, anticonvulsants, tricyclic antidepressants, antihypertensive agents (e.g., guanethidine), vitamins, hypoglycemic agents, tranquilizers, hypnotic preparations, theophylline, and beta blockers. Toxic liver effects have been reported with a combination of an OC and cyclosporin A. *CARCINOGENESIS* See Warnings. *PREGNANCY* Pregnancy category X. See Contraindications and Warnings. *NURSING MOTHERS* See Warnings. **Adverse Reactions** An increased risk of the following serious adverse reactions has been associated with OC use (see Warnings): thrombophlebitis, thrombosis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, mesenteric thrombosis, liver tumors, cerebral hemorrhage, hypertension, gall bladder disease, congenital anomalies, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis, Budd-Chiari syndrome, Raynaud's disease, arterial thromboembolism. The following adverse reactions have been reported in OC users and are believed to be drug related: bleeding irregularities (breakthrough bleeding, spotting, missed menses during treatment, amenorrhea after treatment), gastrointestinal symptoms (nausea, vomiting, bloating, abdominal cramps, colitis), dysmenorrhea, infertility after discontinuance of treatment, edema, chloasma or melasma which may persist after drug is discontinued, breast changes (tenderness, enlargement, and secretion), intolerance to contact lenses, changes in corneal curvature (steepening), change in weight (increase or decrease), change in cervical erosion and cervical secretion, possible diminution of lactation when given immediately postpartum, cholestatic jaundice, migraine, increase in size of uterine leiomyomata, rash (allergic), mental depression, reduced tolerance to carbohydrates, vaginal candidiasis, prolactin-secreting pituitary tumors, chiblains. The following adverse reactions have been reported in OC users and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of hair, erythema multiforme, erythema nodosum, hemorrhagic eruptions, vaginitis, porphyria, impaired renal function, malignant nephrosclerosis (hemolytic uremic syndrome), malignant hypertension, acute renal failure, premature supraventricular contractions. **Information for the Patient** (See Patient Package Insert).

Rev. April 1987

SYNTEX

COLPOSCOPE 1-FC



FULLY CO_2 LASER COMPATIBLE, TODAY OR IN THE FUTURE.

The Colposcope 1-FC features the added convenience of:

- Fine focus mechanism.
- Five-step magnification changer.
- Easy upgrading to documentation equipment.
- Fiber optic light source with green filter.

For additional information, call (800) 442-4020.

Satisfaction realized.

87% patient continuation rate† with Ortho ALL-FLEX* Arcing Spring Diaphragm.

Easy for patient to insert—
the Ortho ALL-FLEX* Diaphragm folds easily.

Easy for patient to correctly position in vagina—
the Ortho ALL-FLEX* Diaphragm can be compressed at any two opposing points around the rim.

Easy to use with **GYNOL II* (2% nonoxynol-9) Contraceptive Jelly**—
greaseless, odorless spermicide.

Easy to clean—one-step molding process eliminates gap between spring and dome so jelly or secretions can't accumulate.

Ortho ALL-FLEX*
DIAPHRAGM

†Percentage of patients continuing the method for 12 consecutive months.

Consult the revised patient brochure for new information on Toxic Shock Syndrome (TSS) and wearing time.

Clinical Opinion

Missed abortion: Still appropriate terminology? 261
Gabriella Pridjian, MD, and Atef H. Moawad, MD
Chicago, Illinois

In modern obstetrics, timely use of ultrasonography in early pregnancy has made the use of the term *missed abortion* no longer appropriate.

Multidisciplinary team counseling for fetal anomalies 263
Robert P. Lorenz, MD, and Margueritte H. Kuhn, MD
Royal Oak and Detroit, Michigan

When a fetal anomaly occurs, a multidisciplinary team of specialists assists the obstetrician in planning and counseling a family in an effective new program to assist in this family crisis.

Breast disease programs in obstetrics and gynecology: A plea for training in mammography 267
Norbert Gleicher, MD
Chicago, Illinois

The inclusion of mammography training programs within obstetrics and gynecology curricula is proposed as an integral step in the establishment of teaching programs in breast disease.

Intrauterine growth retardation: Standards for diagnosis 271
Robert L. Goldenberg, MD, Gary R. Cutter, PhD, Howard J. Hoffman, MA, Judith M. Foster, MPH, Kathleen G. Nelson, MD, and John C. Hauth, MD
Birmingham, Alabama

The methodology used to develop the current standards for defining intrauterine growth retardation were evaluated, and, on the basis of these findings, recommendations are made to develop a single national standard for the diagnosis of intrauterine growth retardation.

OBSTETRICS/GYNECOLOGY REPORT

The depth of texts, the timeliness of journals . . .

OBSTETRICS/GYNECOLOGY REPORT, a **new** resource that works for **you**, is a synthesis of current information on the most important clinical developments in the field. The REPORT makes it **convenient** for the busy practitioner to stay up to date.

- Three issues every 12 months.
- Each issue focuses on two main topics within the specialty:

Vol. 1, No. 1	Infectious diseases Reproductive endo-fertility
Vol. 1, No. 2	Fetal monitoring Human papilloma virus
Vol. 1, No. 3	Breast disease Urinary incontinence

- Comprehensive coverage of the selected topics, from new developments to cases of interest.
- Approximately 150 pages per issue; no advertisements.
- Attractive, two-color format throughout.

Our editorial board of prominent physicians is committed to offering you an insightful, reliable, and practical resource that truly is beneficial to clinical practice.

Clinical Articles

Anal and perianal abnormalities in prepubertal victims of sexual abuse 278
David Muram, MD
Memphis, Tennessee

Perianal abnormalities were observed in one third of children who were sexually abused.

Phosphorus 31 nuclear magnetic resonance examination of female reproductive tissues 282
Elizabeth A. Noyszewski, MSc, Jyothi Raman, MSc, Suzanne R. Trupin, MD, Barbara L. McFarlin, CNM, MS, and M. Joan Dawson, PhD
Urbana, Illinois

Noninvasive nuclear magnetic resonance spectroscopy examination may be a useful addition to magnetic resonance imaging, and it could become a cost-effective method of evaluating biopsy samples biochemically.

A new surgical technique to treat refractory labial fusion in the elderly 289
N. Johnson, MRCOG, FRCS, R. J. Lilford, MRCOG, MRCP, PhD, and D. Sharpe, FRCS, OBE
Leeds and Bradford, England

A new treatment of refractory labial fusion is described, in which a skin flap from the thigh is used to cover the raw area.

Predictive values, relative risks, and overall benefits of high and low maternal serum α-fetoprotein screening in singleton pregnancies: New epidemiologic data 291
Aubrey Milunsky, MB, BCh, DSc, Susan S. Jick, MPH, Carol L. Bruell, MS, Dean S. MacLaughlin, PhD, Yean-Kai Tsung, PhD, Hershel Jick, MD, Kenneth J. Rothman, DrPH, and Walter Willett, MD
Boston, Massachusetts

In addition to detection of pregnancies in which the fetus has a neural tube or chromosome defect, maternal serum α-fetoprotein screening is shown in this study to also be useful in the identification of high-risk pregnancy.

The efficacy of fetal sonographic biometry in Down syndrome screening 297
Mark T. Peters, MD, Charles J. Lockwood, MD, and Wayne A. Miller, MD
Lincoln and Boston, Massachusetts

Fetal sonographic biometry cannot be used as a sole criterion for Down syndrome screening.

Pregnancy loss in a small chorionic villus sampling series 301
Brian A. Clark, PhD, MD, John M. Bissonnette, MD, Susan B. Olson, PhD, and R. Ellen Magenis, MD
Portland, Oregon

The pregnancy loss rate in the initial 211 chorionic villus sampling cases does not support the contention that there is an initial high rate of pregnancy loss.

Maternity shelter care for adolescents: Its effect on incidence of low birth weight 303
Katherine D. LaGuardia, MD, MPH, Maurice L. Druzin, MD, and Carol Eades, BA
New York, New York

A retrospective analysis of 225 pregnant adolescents revealed that those living in a maternity shelter yet receiving identical medical care as those living at home were delivered of significantly fewer infants of low birth weight and preterm gestation.

Fetal hyperinsulinism in anencephaly 306
C. Hubinont, MD, PhD, N. M. Fisk, MD, U. Nicolini, MD, and C. H. Rodeck, MD
London, England

In utero hyperinsulinism present in anencephalic fetuses could be responsible for their subnormal growth despite an absent hypothalamohypophysial axis.

Antenatal ultrasonographic diagnosis of fetal seizure activity 308
Helain J. Landy, MD, Alfred N. Khoury, MD, and Peter S. Heyl, MD
Washington, D.C., and Fairfax, Virginia

The ultrasonographic diagnosis of in utero seizures in a chromosomally normal, growth-retarded fetus is reported.

Contents

Phase II trial of ifosfamide and mesna in mixed mesodermal tumors of the uterus (A Gynecologic Oncology Group Study) 309
Gregory P. Sutton, MD, John A. Blessing, PhD, Neil Rosenshein, MD, Guy Photopulos, MD, and Philip J. DiSaia, MD
Indianapolis, Indiana, Buffalo, New York, Baltimore, Maryland, Memphis, Tennessee, and Orange, California

Ifosfamide and mesna produced a 32.2% response rate with a 17.9% complete response rate in advanced or recurrent mixed mesodermal tumors of the uterus.

Ceramide lactoside in amniotic fluid: High concentration in chorioamnionitis and in preterm labor 313
Mikko Hallman, MD, DrMedSci, Kristiina Bry, MD, and Olli Pitkänen, MD
Helsinki, Finland

Cermide lactoside may serve as a sensitive and specific marker of inflammation in fetal membranes during preterm labor.

Cardiac isoenzymes and electrocardiographic changes during ritodrine tocolysis 318
Hamid A. Hadi, MD, and Sabah J. Albazzaz, MD
Augusta, Georgia

Serially determined cardiac isoenzymes and electrocardiographic examinations during ritodrine tocolysis suggest that this drug in the recommended regimen does not produce direct myocardial damage.

Elevated liver enzymes and thrombocytopenia in the third trimester of pregnancy: An unusual case report and a review of the literature 322
Mary E. Hannah, MSc, MDCM, Ron Gonen, MD, Eva J. M. Mocarski, MSc, MD, Ross Cameron, MD, Laurence Blendis, MD, and Michael Glynn, MD
Toronto, Ontario, Canada

Abdominal pain, thrombocytopenia, and elevated liver enzymes, occurring in a twin pregnancy and diagnosed as preeclampsia on liver biopsy, resolved before delivery.

Continuous tissue pH monitoring in the term fetus 323
Mary L. Small, MD, Marie Beall, MD, Lawrence D. Platt, MD, Diane Dirks, RN, and Howard Hochberg, MD
Los Angeles, California

Continuous tissue pH monitoring of 59 patients showed poor correlation with scalp pH; however, knowing the trend of tissue pH is thought to be worthwhile.

Noninvasive management of isolated bilateral fetal hydrothorax 330
Leen Pijpers, MD, PhD, Annette Reuss, MD, Patricia A. Stewart, NDCT, CCPT, and Juriy W. Wladimiroff, MD, PhD
Rotterdam, The Netherlands

Normal neonatal outcome was observed in eight cases of bilateral isolated fetal hydrothorax in which a noninvasive management approach was adopted.

(Contents continued on page 10A)

Contents continued from page 9A

Relapsing polychondritis in pregnancy: A case report and review 332
Martin L. Gimovsky, MD, and Mark Nishiyama, MD
Los Angeles, California

A case of chronic pulmonary insufficiency during gestation is described.

Abscess of allantoic duct remnant 334
I. Cori Baill, MD, G. William Moore, MD, PhD, and Lora A. Hedrick, MD
Baltimore, Maryland

Funicitis and an abscessed allantoic duct remnant were present in an umbilical cord at 22 1/7 weeks' gestation.

Infection and labor. IV. Cachectin–tumor necrosis factor in the amniotic fluid of women with intraamniotic infection and preterm labor 336
Roberto Romero, MD, Kirk R. Manogue, PhD, Murray D. Mitchell, DPhil, Ying King Wu, MD, Enrique Oyarzun, MD, John C. Hobbins, MD, and Anthony Cerami, PhD
New Haven, Connecticut, New York, New York, and Salt Lake City, Utah

Tumor necrosis factor may play a role in the onset of preterm labor in women with intraamniotic infection.

Pulsed Doppler flow-velocity waveforms in the prediction of fetal hematocrit of the severely isoimmunized pregnancy 341
Joshua A. Copel, MD, Peter A. Grannum, MD, Jacqueline J. Green, MS, RDMS, Kathy Belanger, PhD, and John C. Hobbins, MD
New Haven, Connecticut

Two previously reported formulas relating fetal hematocrit to Doppler indices were evaluated prospectively and were found not to predict hematocrit reliably.

Concurrence of mouthing movement and rapid eye movement/non–rapid eye movement phases with advance in gestation of the human fetus 344
Naoki Horimoto, MD, Takashi Koyanagi, MD, Shin Nagata, MD, Hiromasa Nakahara, MD, and Hitoo Nakano, MD
Fukuoka, Japan

By ultrasonographic observation of 26 human fetuses between 28 and 41 weeks of gestation, regular mouthing movement was found to concur with the non–rapid eye movement period from 35 weeks' gestation to term.

Fetal heart rate patterns in red blood cell isoimmunized pregnancies 351
K. H. Nicolaides, BSc, MD, G. Sadovsky, MD, and E. Cetin, MD
London, England

Fetal heart rate patterns in 33 red blood cell isoimmunized pregnancies were related to oxygenation and hemoglobin concentration of fetal blood obtained at cordocentesis.

Contents

Plasma atrial natriuretic peptide in human fetus: Response to intravascular blood transfusion 357
Marios Z. Panos, MD, Kypros H. Nicolaides, MD, John V. Anderson, MD, Demetrios L. Economides, MD, Lesley Rees, MD, and Roger Williams, MD
London, England

Human fetal plasma atrial natriuretic peptide concentration rises in response to intravascular blood transfusion.

Fetal cardiac output in the isoimmunized pregnancy: A pulsed Doppler-echocardiographic study of patients undergoing intravascular intrauterine transfusion 361
Joshua A. Copel, MD, Peter A. Grannum, MD, Jacqueline J. Green, MS, RDMS, Kathy Belanger, PhD, Nagui Hanna, MD, C. Carl Jaffe, MD, John C. Hobbins, MD, and Charles S. Kleinman, MD,
New Haven, Connecticut

Cardiac output was measured in a group of isoimmunized fetuses undergoing intravascular transfusion and was found to be significantly higher than in controls.

Twin-to-twin transfusion syndrome: What are appropriate diagnostic criteria? 365
Fiona H. Danskin, MB, ChB, and James P. Neilson, MD
Glasgow, Scotland

The standard diagnostic criteria for the chronic twin-to-twin transfusion syndrome were reevaluated in a study of 178 consecutive twin pregnancies, and it was concluded that a definitive diagnosis of this syndrome cannot be made with these criteria alone.

The prevalence and biologic significance of lupus anticoagulant and anticardiolipin antibodies in a general obstetric population 369
C. J. Lockwood, MD, R. Romero, MD, R. F. Feinberg, MD, PhD, L. P. Clyne, FIMLS, MS, B. Coster, BS, and J. C. Hobbins, MD
New Haven, Connecticut

In a low-risk obstetric population the prevalence of lupus anticoagulant and antiphospholipid antibodies was 0.27% and 2.2%, respectively, with normal outcomes observed in 25% of affected patients.

Fetal blood gas analysis from cordocentesis for abnormal fetal heart rate patterns 374
Dinesh M. Shah, MD, and Frank H. Boehm, MD
Nashville, Tennessee

Three cases that involve dilemmas from lack of synchrony of fetal heart rate tracing, cordocentesis-obtained blood gas analysis, and postnatal blood gas analysis are presented.

Presence of autoantibodies in women with unexplained infertility 377
Pamela V. Taylor, PhD, James M. Campbell, MRCOG, and James S. Scott, MD
Leeds, England

Unexplained infertility was studied in 41 patients and was shown to be associated with a significantly higher prevalence of autoantibodies to smooth muscle, phospholipid, and some nuclear antigens, compared with normal pregnancy.

(Contents continued on page 12A)

Contents continued from page 11A

Successful twin pregnancy after embryo donation to a patient with XY gonadal dysgenesis 380
Mark V. Sauer, MD, Rogerio A. Lobo, MD, and Richard J. Paulson, MD
Los Angeles, California

A twin pregnancy was accomplished in a patient with XY gonadal dysgenesis with the use of donated oocytes obtained by transvaginal aspiration, fertilized in vitro, and replaced transcervically.

Ovarian hyperstimulation presenting as acute hydrothorax after in vitro fertilization 381
Charles R. Kingsland, MB, ChB, John V. Collins, MD, Botros Rizk, MB, ChB, and Bridgett A. Mason, MB, BS
London, England

This is the first reported case of acute hydrothorax as the only presenting sign of ovarian hyperstimulation after in vitro fertilization.

Normal amniotic fluid volume changes throughout pregnancy 382
Robert A. Brace, PhD, and Edward J. Wolf, MD
La Jolla, California

A total of 705 measured amniotic fluid volumes in normal human pregnancies was used to statistically characterize gestational changes in amniotic fluid volume.

Doppler velocimetry and placental disease 388
Luis A. Bracero, MD, Debra Beneck, MD, Nancy Kirshenbaum, MD, Marianne Peiffer, RDMS, Patricia Stalter, CDMS, and Harold Schulman, MD
Valhalla and Mineola, New York

An elevated umbilical artery systolic-diastolic ratio was found to be associated with a decrease in the number of small muscular arteries within the placenta.

Local methotrexate injection: A nonsurgical treatment of ectopic pregnancy 393
Mordechai Pansky, MD, Ian Bukovsky, MD, Abraham Golan, MD, Rami Langer, MD, David Schneider, MD, Shlomo Arieli, MD, and Eliahu Caspi, MD
Zerifin, Israel

Twenty-seven patients with unruptured tubal pregnancy were treated by local injection of methotrexate at laparoscopy; all but three, who needed laparotomy because of rising titers of β-hCG, recovered uneventfully.

Serial human chorionic gonadotropin determinations by fluoroimmunoassay for differentiation between intrauterine and ectopic gestation 397
Bo Lindblom, MD, PhD, Mats Hahlin, MD, and Peter Sjöblom, PhD
Göteborg, Sweden

Improved analysis of hCG patterns increases accuracy in diagnosis of ectopic pregnancy.

Contents

Dandy-Walker syndrome: A review of fifteen cases evaluated by prenatal sonography 401

Paul D. Russ, MD, Dolores H. Pretorius, MD, and Mark J. Johnson, MD

Denver, Colorado, San Diego, California, and Columbus, Ohio

Fifteen cases of Dandy-Walker syndrome diagnosed in utero were reviewed to determine the spectrum of prenatal sonographic findings, associated congenital anomalies, and clinical outcome.

The frequency and management of uterine perforations during first-trimester abortions 406

Steven G. Kaali, MD, Ivan A. Szigetvari, MD, PhD, and George S. Bartfai, MD, PhD

Dobbs Ferry, New York

First-trimester abortions combined with laparoscopic sterilizations indicate that the rate of unsuspected uterine perforations is manyfold higher than previously believed, and observation rather than further surgery is suggested

Histologic and immunologic study of uterine biopsy tissue of women with incipient abortion 409

Magdy Michel, MB, MRCOG, Jenny Underwood, BSc, David A. Clark, MD, PhD, FRCPC, James F. Mowbray, MD, FRCP, and Richard W. Beard, MD, FRCOG

London, England, and Hamilton, Ontario, Canada

Biopsy specimens of decidua from women with incipient first-trimester spontaneous miscarriage showed a morphologic change in granulated mononuclear cell populations and a decreased ability to release soluble immunosuppressive factors in culture.

Randomized trial of diet versus diet plus cardiovascular conditioning on glucose levels in gestational diabetes 415

Lois Jovanovic-Peterson, MD, Eric P. Durak, MSc, and Charles M. Peterson, MD

Santa Barbara, California, and New York, New York

Arm ergometry is a safe and efficacious form of adjunctive therapy for the gestational diabetic woman.

Thrombosis prophylaxis in pregnancy with use of subcutaneous heparin adjusted by monitoring heparin concentration in plasma 420

Thomas C. Dahlman, MD, Margareta S. E. Hellgren, MD, and Margareta Blombäck, MD

Stockholm, Sweden

Anti–factor Xa activity can be used for monitoring the increasing need for heparin during a low-dose heparin regimen, but the activated partial thromboplastin time method is too insensitive.

Early pregnancy glycosylated hemoglobin, severity of diabetes, and fetal malformations 426
Michael J. Lucas, MD, Kenneth J. Leveno, MD, M. Lynne Williams, RN, Philip Raskin, MD, and Peggy J. Whalley, MD
Dallas, Texas

Malformation outcome among insulin-treated diabetic women was related both to early glycohemoglobin level and to White classification.

Predictive value of increased plasma levels of fibronectin in gestational hypertension 432
Véronique Ballegeer, MD, Bernard Spitz, MD, Lena Kieckens, Huberte Moreau, André Van Assche, MD, and Désiré Collen, MD, PhD
Leuven, Belgium

Increased plasma fibronectin levels (>140% of normal) predict the development of gestational hypertension in primigravid women with a sensitivity and specificity of 95%.

Zinc, cadmium, and hypertension in parturient women 437
Noam Lazebnik, MD, Betty R. Kuhnert, PhD, and Paul M. Kuhnert, PhD, MD
Cleveland, Ohio

Maternal plasma zinc, placental zinc, and the relationship between whole blood cadmium and plasma zinc is altered in preeclamptic toxemia but not in chronic hypertension.

Erythrocyte cation metabolism in preeclampsia 441
James R. Sowers, MD, Michael B. Zemel, PhD, Richard A. Bronsteen, MD, Paula C. Zemel, PhD, Mary F. Walsh, PhD, Paul R. Standley, MS, and Robert J. Sokol, MD
Detroit, Michigan

The relationship between blood pressure and erythrocyte cation metabolism is explored in black women with pregnancy-induced hypertension.

BASIC SCIENCE SECTION

Immunoregulatory activity in supernatants from cultures of normal human trophoblast cells of the first trimester 446
Mrinal K. Sanyal, PhD, Charles J. Brami, MD, Paul Bischof, PhD, Edwina Simmons, MD, Eytan R. Barnea, MD, John M. Dwyer, MD, PhD, and Frederick Naftolin, MD, DPhil
New Haven, Connecticut, and Geneva, Switzerland

Placental trophoblast cells of human first-trimester pregnancy secreted an immunosuppressive factor in culture, and this factor may be associated with the immunoregulation and maintenance of fetal allograft during early gestation.

Contents

Increased myometrial responsiveness to oxytocin during term and preterm labor 454
R. E. Garfield, PhD, and S. Beier, PhD
Hamilton, Ontario, Canada, and Berlin, West Germany

During term and preterm labor in rats, oxytocin dose–myometrial response curves showed increased maximal tension and steeper slopes but no change in pD_2 values (i.e., sensitivity).

CA 125 in the epithelium closely related to the embryonic ectoderm: The periderm and the amnion 462
Yoshihiko Nanbu, MD, Shingo Fujii, MD, Ikuo Konishi, MD, Hirofumi Nonogaki, MD, and Takahide Mori, MD
Kyoto, Japan

In addition to the fetal coelomic epithelium–related tissues, the amnion and the periderm, both of which constitute the epithelia covering the amniotic cavity, produce CA 125.

Power spectrum analysis of myometrial electromyogram and intrauterine pressure changes in the pregnant rhesus monkey in late gestation 467
Hsing Wen Hsu, BS, Jorge P. Figueroa, MD, PhD, M. Barbera O. M. Honnebier, MD, Richard Wentworth, PhD, and Peter W. Nathanielsz, MD, PhD
Ithaca, New York

Power spectrum analysis of myometrial electromyogram and intrauterine pressure is used to distinguish and quantify contracture and contraction-type myometrial activity in pregnant rhesus monkeys in late gestation.

Pattern of human chorionic gonadotropin binding in the polycystic ovary 474
James Brawer, PhD, Martine Richard, MSc, and Riaz Farookhi, PhD
Montreal, Quebec, Canada

This study describes the histologic features and the LH-hCG binding capacity of structures that make up the experimentally induced polycystic ovary.

Effect of a 48-hour intravenous Δ^4-androstenedione infusion on the pregnant rhesus monkey in the last third of gestation: Changes in maternal plasma estradiol concentrations and myometrial contractility 481
Jorge P. Figueroa, MD, PhD, M. Barbera O. M. Honnebier, MD, Zbigniew Binienda, DVM, Jeffrey Wimsatt, DVM, and Peter W. Nathanielsz, MD, PhD
Ithaca, New York

Infusion of androstenedione for 48 hours into pregnant rhesus monkeys in late gestation significantly elevated maternal plasma estrogen levels and was accompanied by increased myometrial activity.

(Contents continued on page 16A)

Contents continued from page 15A

Flow cytometry of normal, hyperplastic, and malignant human endometrium 487
James G. Thornton, MD, Philip Quirke, PhD, and Michael Wells, MD
Leeds, England

Flow cytometric proliferative indices from endometrial hyperplasias and carcinomas correlate with S-phase labeling indices and tissue differentiation.

Atrial natriuretic peptide receptors in guinea pig placentas 493
Christos G. Hatjis, MD, and David M. Grogan, BA
Winston-Salem, North Carolina

In guinea pig placentas and subplacentas, the affinity of atrial natriuretic peptide receptors for atrial natriuretic peptide changes from 45 to 65 days' gestation.

INFORMATION FOR AUTHORS

Information for authors 25A

Index to advertisers on page 55A

Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Prices include shipping. *Payment must accompany all orders and must be in U.S. funds, drawn on a U.S. bank.*

Contact The C.V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318 USA; phone (314) 872-8370, ext. 394. In the U.S., call toll-free: 1-800-325-4177, ext. 394. Please allow six weeks for delivery.

The JOURNAL is abstracted and/or indexed in *Index Medicus, Science Citation Index, Current Contents/Clinical Medicine, Current Contents/Life Sciences, Excerpta Medica, BRS Colleague,* and MEDLINE.

Authorization to photocopy items for internal or personal use, or the internal or personal use of specific clients, is granted by The C.V. Mosby Company for libraries and other users registered with the Copyright Clearance Center (CCC) Transactional Reporting Service, provided that 10¢ per page per copy is paid directly to CCC, 27 Congress St., Salem, MA 01970; phone (508)744-3350. The U.S. Government retains a nonexclusive, royalty-free license in and to any copyright on articles authored by government employees. 0002-9378/89 $00.00 + .10.

"It's still like walking the high wire, but now I have a safety net."

More confidence in presumptive antibiotic therapy. Prescribing UNASYN presumptively is a step you can take with confidence. UNASYN covers gram-positives (even enterococci), prevalent gram-negatives, and anaerobes: The right combination for most patients with common mixed infections.*

And UNASYN minimizes safety concerns with a reliable penicillin-class profile.[1] (However, UNASYN is contraindicated in penicillin-allergic patients.)

Expect strong support from UNASYN in the mixed infections* you face every day.

Join a Leader
We're The Ohio Permanente Medical Group, Inc.

and we are looking for board certified/board eligible **Obstetrician/Gynecologists** to help us keep up with rapid growth of the Kaiser Permanente Program in Northeastern Ohio. OPMG is the multispecialty group practice that provides health care services to the more than 185,000 Kaiser members in the Cleveland-Akron area.

Our wealth of experience of over 40 plus years (25 in Ohio) makes Kaiser Permanente a mature, solid, leader in the managed care sector of the health care industry. The rewards of practice with us are substantial—excellent salary and benefit packages, company-paid retirement plan, full malpractice coverage, a stimulating, collegial environment in which to practice quality medicine, and more.

Kaiser Permanente's Ohio Region is located in the heart of the dynamic, resurgent industrial Midwest. The area offers the best of big city sophistication and culture in an affordable, accessible living area.

Please send your resume to: Ronald G. Potts, M.D., Medical Director, Ohio Permanente Medical Group, Inc., 1300 E. 9th Street, Suite 1100, Cleveland, OH 44114. Or you may call us collect at (216) 623-8780.

KAISER PERMANENTE®

PERINATAL GENETICIST

The Department of Obstetrics and Gynecology at Pennsylvania Hospital is seeking an obstetrician with genetic fellowship training to join an active perinatal genetics program.

Skills in second trimester amniocentesis, chorionic villus sampling, and Level II ultrasound are desired.

Responsibilities include resident and medical student education and active clinical practice with a University Appointment at the level of Assistant Professor.

Please send resumes to:

Ronald J. Bolognese, M.D.
Department of Obstetrics
and Gynecology
Pennsylvania Hospital
8th & Spruce Streets
Philadelphia, PA 19107

INDICATIONS AND USAGE
UNASYN is indicated for the treatment of infections due to susceptible strains of the designated microorganisms in the conditions listed below.
Skin and Skin Structure Infections caused by beta-lactamase producing strains of *Staphylococcus aureus*, *Escherichia coli*,* *Klebsiella* spp.* (including *K. pneumoniae**), *Proteus mirabilis*,* *Bacteroides fragilis*,* *Enterobacter* spp.,* and *Acinetobacter calcoaceticus*.*
Intra-Abdominal Infections caused by beta-lactamase producing strains of *Escherichia coli*, *Klebsiella* spp. (including *K. pneumoniae**), *Bacteroides* spp. (including *B. fragilis*), and *Enterobacter* spp.*
Gynecological Infections caused by beta-lactamase producing strains of *Escherichia coli*,* and *Bacteroides* spp.* (including *B. fragilis**).
*Efficacy for this organism in this organ system was studied in fewer than 10 infections.
While UNASYN* (ampicillin sodium/sulbactam sodium) is indicated only for the conditions listed above, infections caused by ampicillin-susceptible organisms are also amenable to treatment with UNASYN due to its ampicillin content. Therefore, mixed infections caused by ampicillin-susceptible organisms and beta-lactamase producing organisms susceptible to UNASYN should not require the addition of another antibiotic.

CONTRAINDICATIONS
The use of UNASYN is contraindicated in individuals with a history of hypersensitivity reactions to any of the penicillins.

WARNINGS
SERIOUS AND OCCASIONALLY FATAL HYPERSENSITIVITY (ANAPHYLACTIC) REACTIONS HAVE BEEN REPORTED IN PATIENTS ON PENICILLIN THERAPY. THESE REACTIONS ARE MORE APT TO OCCUR IN INDIVIDUALS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY AND/OR HYPERSENSITIVITY REACTIONS TO MULTIPLE ALLERGENS. THERE HAVE BEEN INDIVIDUALS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY WHO HAVE EXPERIENCED SEVERE REACTIONS WHEN TREATED WITH CEPHALOSPORINS. BEFORE THERAPY WITH A PENICILLIN, CAREFUL INQUIRY SHOULD BE MADE CONCERNING PREVIOUS HYPERSENSITIVITY REACTIONS TO PENICILLINS, CEPHALOSPORINS, AND OTHER ALLERGENS. IF AN ALLERGIC REACTION OCCURS, UNASYN SHOULD BE DISCONTINUED AND THE APPROPRIATE THERAPY INSTITUTED.
SERIOUS ANAPHYLACTOID REACTIONS REQUIRE IMMEDIATE EMERGENCY TREATMENT WITH EPINEPHRINE, OXYGEN, INTRAVENOUS STEROIDS, AND AIRWAY MANAGEMENT, INCLUDING INTUBATION, SHOULD ALSO BE ADMINISTERED AS INDICATED.

PRECAUTIONS
General: A high percentage of patients with mononucleosis who receive ampicillin develop a skin rash. Thus, ampicillin class antibiotics should not be administered to patients with mononucleosis. In patients treated with UNASYN the possibility of superinfections with mycotic or bacterial pathogens should be kept in mind during therapy. If superinfections occur (usually involving *Pseudomonas* or *Candida*), the drug should be discontinued and/or appropriate therapy instituted.
Drug Interactions: Probenecid decreases the renal tubular secretion of ampicillin and sulbactam. Concurrent use of probenecid with UNASYN may result in increased and prolonged blood levels of ampicillin and sulbactam. The concurrent administration of allopurinol and ampicillin increases substantially the incidence of rashes in patients receiving both drugs as compared to patients receiving ampicillin alone. It is not known whether this potentiation of ampicillin rashes is due to allopurinol or the hyperuricemia present in these patients. There are no data with UNASYN and allopurinol administered concurrently. UNASYN and aminoglycosides should not be reconstituted together due to the *in vitro* inactivation of aminoglycosides by the ampicillin component of UNASYN.
Drug/Laboratory Test Interactions: Administration of UNASYN will result in high urine concentrations of ampicillin. High urine concentrations of ampicillin may result in false positive reactions when testing for the presence of glucose in urine using Clinitest™, Benedict's Solution or Fehling's Solution. It is recommended that glucose tests based on enzymatic glucose oxidase reactions (such as Clinistix™ or Testape™) be used. Following administration of ampicillin to pregnant women, a transient decrease in plasma concentration of total conjugated estriol, estriolglucuronide, conjugated estrone, and estradiol has been noted. This effect may also occur with UNASYN.
Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have not been performed to evaluate carcinogenic or mutagenic potential.
Pregnancy
Pregnancy Category B: Reproduction studies have been performed in mice, rats, and rabbits at doses up to ten (10) times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to UNASYN. There are, however, no adequate and well controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed. (See—Drug/Laboratory Test Interactions.)
Labor and Delivery: Studies in guinea pigs have shown that intravenous administration of ampicillin decreased the uterine tone, frequency of contractions, height of contractions, and duration of contractions. However, it is not known whether the use of UNASYN in humans during labor or delivery has immediate or delayed adverse effects on the fetus, prolongs the duration of labor, or increases the likelihood that forceps delivery or other obstetrical intervention or resuscitation of the newborn will be necessary.
Nursing Mothers: Low concentrations of ampicillin and sulbactam are excreted in the milk; therefore, caution should be exercised when UNASYN is administered to a nursing woman.
Pediatric Use: The efficacy and safety of UNASYN have not been established in infants and children under the age of 12.

ADVERSE REACTIONS
UNASYN is generally well tolerated. The following adverse reactions have been reported:
Local Adverse Reactions
Pain at IM injection site—16% Pain at IV injection site—3%
Thrombophlebitis—3%
Systemic Adverse Reactions
The most frequently reported adverse reactions were diarrhea in 3% of the patients and rash in less than 2% of the patients.
Additional systemic reactions reported in less than 1% of the patients were itching, nausea, vomiting, candidiasis, fatigue, malaise, headache, chest pain, flatulence, abdominal distension, glossitis, urine retention, dysuria, edema, facial swelling, erythema, chills, tightness in throat, substernal pain, epistaxis and mucosal bleeding.
Adverse Laboratory Changes
Adverse laboratory changes without regard to drug relationship that were reported during clinical trials were:
Hepatic: Increased AST (SGOT), ALT (SGPT), alkaline phosphatase, and LDH.
Hematologic: Decreased hemoglobin, hematocrit, RBC, WBC, neutrophils, lymphocytes, platelets and increased lymphocytes, monocytes, basophils, eosinophils, and platelets.
Blood Chemistry: Decreased serum albumin and total proteins.
Renal: Increased BUN and creatinine.
Urinalysis: Presence of RBC's and hyaline casts in urine.
The following adverse reactions have been reported with ampicillin-class antibiotics and can also occur with UNASYN.
Gastrointestinal: Gastritis, stomatitis, black "hairy" tongue, enterocolitis and pseudomembranous colitis.
Hypersensitivity Reactions: Urticaria, erythema multiforme, and an occasional case of exfoliative dermatitis have been reported. These reactions may be controlled with antihistamines and, if necessary, systemic corticosteroids. Whenever such reactions occur, the drug should be discontinued, unless the opinion of the physician dictates otherwise. Serious and occasional fatal hypersensitivity (anaphylactic) reactions can occur with a penicillin (see WARNINGS).
Hematologic: In addition to the adverse laboratory changes listed above for UNASYN, agranulocytosis has been reported during therapy with penicillins. All of these reactions are usually reversible on discontinuation of therapy and are believed to be hypersensitivity phenomena.

ROERIG Pfizer
A division of Pfizer Pharmaceuticals

"I used to think only <u>two</u> things in life were certain."

Nothing comes closer to 100% activity against anaerobes in vitro. It's a fact. Studies have proved no other antibiotic superior to UNASYN in overall antianaerobic activity.[1-10] Not clindamycin. Not metronidazole. Nothing.

And that's nothing to overlook—given the importance of anaerobes in today's mixed infections.

Though clinical results may not always mirror those obtained in vitro, there's a world of confidence in choosing UNASYN for presumptive therapy of the mixed infections* you see every day.

CALCUTTA CENTRAL

OBSTETRICIAN GYNECOLOGIST

Expanding Western Massachusetts staff model Health Maintenance Organization is seeking a full-time Board Certified/Board Eligible Obstetrician/Gynecologist to join a staff of eight (8) physicians and six (6) midwives.

Our multi-specialty group practice employs seventy (70) full-time physicians and provides care for a growing membership of over 70,000 from modern suburban facilities, in-patient care is provided at 900-bed Tufts affiliated teaching hospital.

Attractive Pioneer Valley location with fine educational, cultural and recreational opportunities. Excellent salary and comprehensive benefit program. Please send curriculum vitae to: Oded Rencus, M.D., Chief of OB/GYN, 305 Bicentennial Highway, Springfield, MA 01118.

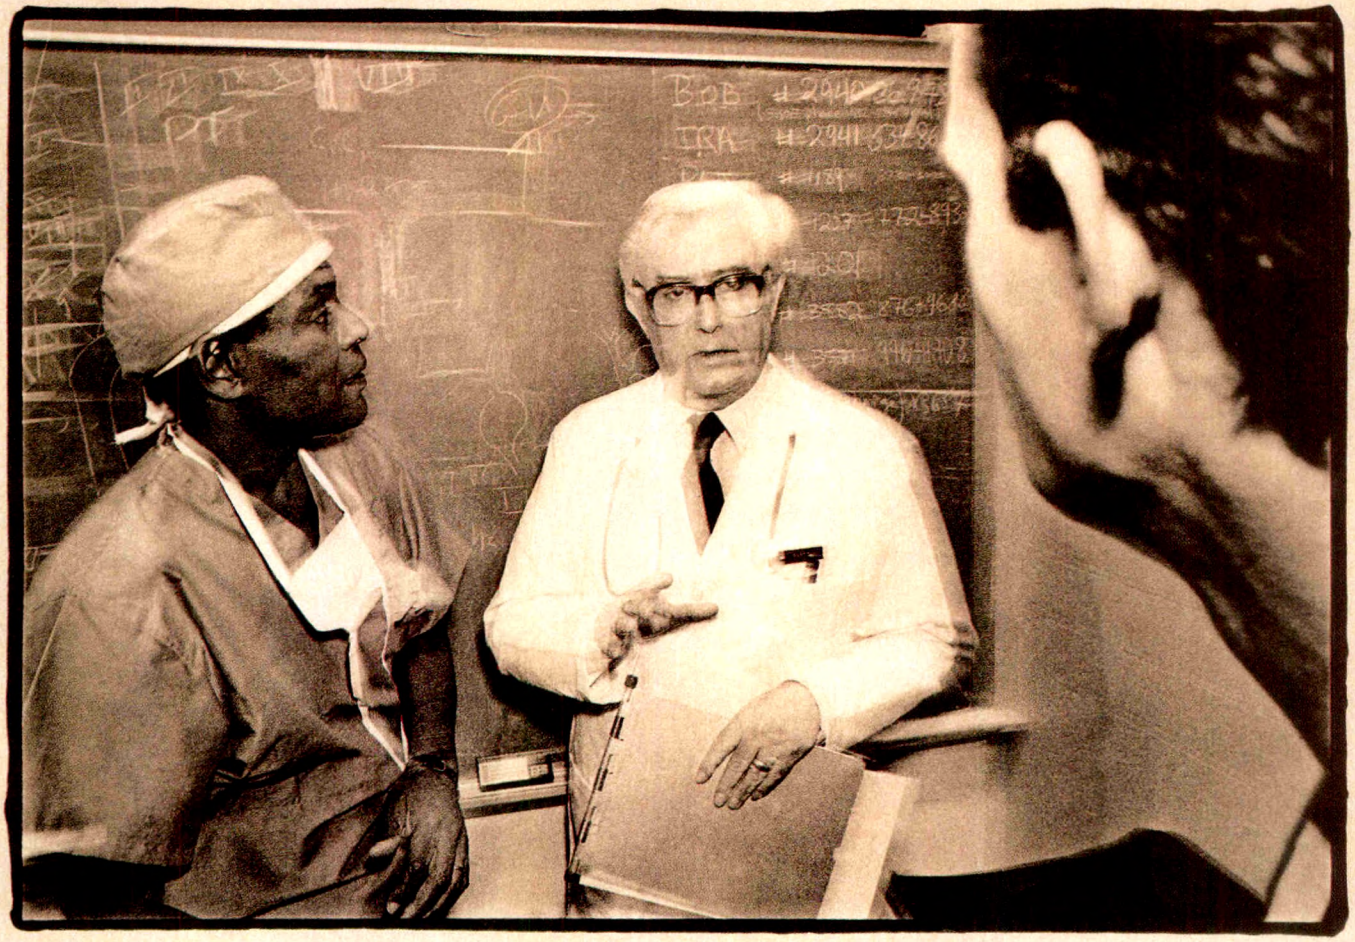
Presented at a symposium entitled *β-Lactamase Inhibitors: Progress with Ampicillin/Sulbactam*, Atlanta, December 6, 1987, p 14 (abs).

INDICATIONS AND USAGE
UNASYN is indicated for the treatment of infections due to susceptible strains of the designated microorganisms in the conditions listed below.
Skin and Skin Structure Infections caused by beta-lactamase producing strains of *Staphylococcus aureus*, *Escherichia coli*,* *Klebsiella* spp.* (including *K. pneumoniae**), *Proteus mirabilis*,* *Bacteroides fragilis*,* *Enterobacter* spp.,* and *Acinetobacter calcoaceticus*.*
Intra-Abdominal Infections caused by beta-lactamase producing strains of *Escherichia coli*, *Klebsiella* spp. (including *K. pneumoniae**), *Bacteroides* spp. (including *B. fragilis*), and *Enterobacter* spp.*
Gynecological Infections caused by beta-lactamase producing strains of *Escherichia coli*,* and *Bacteroides* spp.* (including *B. fragilis**).
*Efficacy for this organism in this organ system was studied in fewer than 10 infections.
While UNASYN* (ampicillin sodium/sulbactam sodium) is indicated only for the conditions listed above, infections caused by ampicillin-susceptible organisms are also amenable to treatment with UNASYN due to its ampicillin content. Therefore, mixed infections caused by ampicillin-susceptible organisms and beta-lactamase producing organisms susceptible to UNASYN should not require the addition of another antibiotic.

CONTRAINDICATIONS
The use of UNASYN is contraindicated in individuals with a history of hypersensitivity reactions to any of the penicillins.



WARNINGS
SERIOUS AND OCCASIONALLY FATAL HYPERSENSITIVITY (ANAPHYLACTIC) REACTIONS HAVE BEEN REPORTED IN PATIENTS ON PENICILLIN THERAPY. THESE REACTIONS ARE MORE APT TO OCCUR IN INDIVIDUALS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY AND/OR HYPERSENSITIVITY REACTIONS TO MULTIPLE ALLERGENS. THERE HAVE BEEN INDIVIDUALS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY WHO HAVE EXPERIENCED SEVERE REACTIONS WHEN TREATED WITH CEPHALOSPORINS. BEFORE THERAPY WITH A PENICILLIN, CAREFUL INQUIRY SHOULD BE MADE CONCERNING PREVIOUS HYPERSENSITIVITY REACTIONS TO PENICILLINS, CEPHALOSPORINS, AND OTHER ALLERGENS. IF AN ALLERGIC REACTION OCCURS, UNASYN SHOULD BE DISCONTINUED AND THE APPROPRIATE THERAPY INSTITUTED.
SERIOUS ANAPHYLACTOID REACTIONS REQUIRE IMMEDIATE EMERGENCY TREATMENT WITH EPINEPHRINE. OXYGEN, INTRAVENOUS STEROIDS, AND AIRWAY MANAGEMENT, INCLUDING INTUBATION, SHOULD ALSO BE ADMINISTERED AS INDICATED.

PRECAUTIONS
General: A high percentage of patients with mononucleosis who receive ampicillin develop a skin rash. Thus, ampicillin class antibiotics should not be administered to patients with mononucleosis. In patients treated with UNASYN the possibility of superinfections with mycotic or bacterial pathogens should be kept in mind during therapy. If superinfections occur (usually involving *Pseudomonas* or *Candida*), the drug should be discontinued and/or appropriate therapy instituted.
Drug Interactions: Probenecid decreases the renal tubular secretion of ampicillin and sulbactam. Concurrent use of probenecid with UNASYN may result in increased and prolonged blood levels of ampicillin and sulbactam. The concurrent administration of allopurinol and ampicillin increases substantially the incidence of rashes in patients receiving both drugs as compared to patients receiving ampicillin alone. It is not known whether this potentiation of ampicillin rashes is due to allopurinol or the hyperuricemia present in these patients. There are no data with UNASYN and allopurinol administered concurrently. UNASYN and aminoglycosides should not be reconstituted together due to the *in vitro* inactivation of aminoglycosides by the ampicillin component of UNASYN.
Drug/Laboratory Test Interactions: Administration of UNASYN will result in high urine concentrations of ampicillin. High urine concentrations of ampicillin may result in false positive reactions when testing for the presence of glucose in urine using Clinitest™, Benedict's Solution or Fehling's Solution. It is recommended that glucose tests based on enzymatic glucose oxidase reactions (such as Clinistix™ or Testape™) be used. Following administration of ampicillin to pregnant women, a transient decrease in plasma concentration of total conjugated estriol, estriolglucuronide, conjugated estrone, and estradiol has been noted. This effect may also occur with UNASYN.
Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have not been performed to evaluate carcinogenic or mutagenic potential.
Pregnancy
Pregnancy Category B: Reproduction studies have been performed in mice, rats, and rabbits at doses up to ten (10) times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to UNASYN. There are, however, no adequate and well controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed. (See—Drug/Laboratory Test Interactions.)
Labor and Delivery: Studies in guinea pigs have shown that intravenous administration of ampicillin decreased the uterine tone, frequency of contractions, height of contractions, and duration of contractions. However, it is not known whether the use of UNASYN in humans during labor or delivery has immediate or delayed adverse effects on the fetus, prolongs the duration of labor, or increases the likelihood that forceps delivery or other obstetrical intervention or resuscitation of the newborn will be necessary.
Nursing Mothers: Low concentrations of ampicillin and sulbactam are excreted in the milk; therefore, caution should be exercised when UNASYN is administered to a nursing woman.
Pediatric Use: The efficacy and safety of UNASYN have not been established in infants and children under the age of 12.

ADVERSE REACTIONS
UNASYN is generally well tolerated. The following adverse reactions have been reported:
Local Adverse Reactions
Pain at IM injection site—16%; Pain at IV injection site—3%; Thrombophlebitis—3%.
Systemic Adverse Reactions
The most frequently reported adverse reactions were diarrhea in 3% of the patients and rash in less than 2% of the patients.
Additional systemic reactions reported in less than 1% of the patients were: itching, nausea, vomiting, candidiasis, fatigue, malaise, headache, chest pain, flatulence, abdominal distension, glossitis, urine retention, dysuria, edema, facial swelling, erythema, chills, tightness in throat, substernal pain, epistaxis and mucosal bleeding.
Adverse Laboratory Changes
Adverse laboratory changes without regard to drug relationship that were reported during clinical trials were:
Hepatic: Increased AST (SGOT), ALT (SGPT), alkaline phosphatase, and LDH.
Hematologic: Decreased hemoglobin, hematocrit, RBC, WBC, neutrophils, lymphocytes, platelets and increased lymphocytes, monocytes, basophils, eosinophils, and platelets.
Blood Chemistry: Decreased serum albumin and total proteins.
Renal: Increased BUN and creatinine.
Urinalysis: Presence of RBC's and hyaline casts in urine.
The following adverse reactions have been reported with ampicillin-class antibiotics and can also occur with UNASYN:
Gastrointestinal: Gastritis, stomatitis, black "hairy" tongue, enterocolitis and pseudomembranous colitis.
Hypersensitivity Reactions: Urticaria, erythema multiforme, and an occasional case of exfoliative dermatitis have been reported. These reactions may be controlled with antihistamines and, if necessary, systemic corticosteroids. Whenever such reactions occur, the drug should be discontinued, unless the opinion of the physician dictates otherwise. Serious and occasional fatal hypersensitivity (anaphylactic) reactions can occur with a penicillin (see WARNINGS).
Hematologic: In addition to the adverse laboratory changes listed above for UNASYN, agranulocytosis has been reported during therapy with penicillins. All of these reactions are usually reversible on discontinuation of therapy and are believed to be hypersensitivity phenomena.

"We need gold-standard results that don't cost a fortune."

Lower antibiotic costs without lowering your standards. UNASYN costs at least 40% less per day than clindamycin/gentamicin or cefoxitin.[11] Yet UNASYN is at least as effective in a variety of mixed infections.*[3,12-19]

And in some studies versus combination therapy, patients treated with UNASYN spent fewer days in the hospital.[3,16,17]

So, look to UNASYN for highly effective, highly affordable therapy in mixed infections* every day.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1988;108:258-65. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL, and in more detail in the *Guide to Writing for the American Journal of Obstetrics and Gynecology*. The latter may be obtained from The C.V. Mosby Company or the Editors on request.

Manuscript submission. Manuscripts should be submitted to one of the three Editors as follows:

1. **Dr. Brewer**—all manuscripts originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation and The Society of Perinatal Obstetricians.

2. **Dr. Zuspan**—manuscripts from the northeastern quadrant of the United States and from Japan, Israel, Italy, and England, manuscripts written for Clinical Opinion and Current Development, and Letters to the Editors. Dr. Zuspan is responsible for manuscripts from The Society of Perinatal Obstetricians. Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. John A. Read, 9102 Lake Steilacoom Point Road, S.W., Tacoma, WA 98498.

3. **Dr. Quilligan**—manuscripts from the north central states (including Ohio), states west of the Mississippi River, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.

Author's designation of reviewers. When authors submit their manuscripts, they may provide the names and addresses of three reviewers for consideration by the Editors.

Copyright statement. Effective July 1, 1988, all manuscripts must be accompanied by the following written statement, signed by *all* authors: "The undersigned author(s) transfers all copyright ownership of the manuscript [title of article] to The C.V. Mosby Company in the event the work is published. The undersigned author(s) warrants that the article is original; is not under consideration by another publication; and its essential substance, tables, or figures have not been previously published. This restriction does not apply to abstracts or press reports published in connection with scientific meetings. The author(s) confirms the final manuscript has been read and each author's contribution has been approved by the appropriate author. The author(s) responsible for the manuscript must be identified."

Previous publication. If a report by the same author(s) has been previously published in any medium that deals in any respect whatever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. The author(s) should inform the Editor of the circumstances of the two reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and animal experimentation. It is assumed by the Editors that manuscripts emanating from a particular

institution are submitted with the approval of the requisite authority. Human experimentation that requires local institutional approval must have this approval *before the experiment is started* and approval must be so indicated in the Methods section of the submitted manuscript. Reports of experiments on animals must *state in the Methods section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or publisher, and the Editor(s) and publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of glossy prints of illustrations are required.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, and business and home telephone numbers of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, and business and home telephone numbers of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page and key words/phrases. On manuscript page 3 type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors*. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Avoid duplication of text and supporting material. Emphasize only your important observations; do not compare your

Estimating length of manuscripts

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200-word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

observations with those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number are allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (Ann Intern Med 1988;108:258-65). Journal titles should conform to abbreviations used in *Cumulated Index Medicus*.

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Fischermann E, Quilligan EJ, et al. Vaginal delivery following cesarean section—use of oxytocin augmentation and epidural anesthesia. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: James VHT, Folkerd EJ, Bonney RC, Beranek PA, Reed MJ. Factors influencing estrogen production and metabolism in postmenopausal women with endocrine cancer. In: van Herendael HB, Riphagen FE, Goessens L, van der Pas H, eds. The climacteric, an update. Lancaster, England: MTP Press, 1983:29.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. This signed permission must accompany the manuscript when it is submitted to the Editor. Abstracts are not acceptable as numbered references.

Illustrations and tables. Illustrations and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice.

A reasonable number of halftone and line illustrations will be reproduced without charge, but special arrangements must be made with the Editors for *color illustrations* at a cost of $525 per page (one side).

For *color photographs* submit original transparencies and two sets of unmounted prints on glossy (smooth-surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The *top, first author's last name,* and *figure number* must be indicated on the front of each transparency and the back of each print. Consistency in size of illustrations within the article is strongly preferred.

For *black-and-white illustrations* submit three sets of 3×4 inch (minimum) to 5×7 inch (maximum) unmounted, glossy photographic prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints with good black-and-white contrast. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted.

Do not use paper clips or mar the surface of prints in any way.

Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with): author(s) name(s), title of article, number, and top marked clearly.

Figures will be returned only on request by the author.

Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. *If a table or any part thereof has been taken from copyrighted material, a legend to the table must give full credit to the original source.* Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Legends to illustrations. Legends for all figures must be typed double-spaced on paper separate from the text of the manuscript, and these pages must be numbered in sequence after the references. Titles should be included in

the legend, *not* on the print. Original magnifications should be provided. *If an illustration has been taken from copyrighted material, the legend must give full credit to the original source.*

Computer-generated illustrations. *Black-and-white illustrations* submitted must be legible and clearly printed in jet-black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend for the illustration should not appear on the print. On the back of each print the name of the first author and the figure number should be given and the top indicated. Original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color illustrations* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color illustrations. The preparation and submitting of color prints should follow the preceding guidelines for black-and-white computer-generated illustrations.

Permissions. Direct quotations, tables, or illustrations that have appeared in copyrighted material must be accompanied by *written permission* for their use from the copyright owner and original author along with complete information as to source. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article.

Clinical Opinion. Limit of 3000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Correspondence. Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication. All letters should be typed double-spaced. The original and a good photocopy must be submitted. Letters should be sent to Dr. Zuspan.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, The C.V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.

Reprints

Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, The C.V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (314) 872-8370.

—Illustrations, properly labeled (three sets of glossy prints)
—Permission to reproduce published material
—Informed consent for patient photographs

The only journal pr[illegible] review of the entire field

mplete Coverage
ch issue provides a com-
te and systematic review
the past year's devel-
ments in one or two
tions of obstetrics and
necology. Together the six
monthly issues cover the
ire field of obstetrics and
necology.

notated References
th each review, the author
ects and annotates the year's most
nificant papers on that topic, high-
hting the key findings.

Authoritative Reviews
Each section consists of a series of short, highly-illustrated reviews. Using a comprehensive bibliography, leading experts evaluate all new findings in their fields.

World Bibliography
In each issue, the bibliography of current world literature lists all relevant papers published in the past year. It is specially compiled by obstetricians and gynecologists from over 200 journals.

histological sections
ed tissue has been
tudied, firstly to assess the sensitivity of this technique in
comparison with other hybridization procedures such as

a biotin–streptavidin polyalkaline phosphatase comp
detection system; they demonstrated the presence
HPV 6 and 11 in benign condylomas and also in
case of cervical carcinoma HPV 16 was present in
cases of vulval intra-epithelial neoplasia and in four ca
of squamous cancer of the anal canal. Shibata *et al.*
used an enzymatic *in vitro* gene amplification techni
— the polymerase chain reaction; the assay detected H
16 or 18, without cross-reactivity to HPV 6 or 11, in
biopsies from women with severe cervical dysplasia
invasive cancer.

Wilbur *et al.* [5] examined 180 exophytic genital lesi
for HPV by haematoxylin and eosin light microscopy,
munocytochemistry for HPV capsid antigen and *in*
hybridization for HPV messenger RNA. Of 96 histolo
cally confirmed condylomas, *in situ* hybridization
positive in 80 (83%), the predominant types being H
6 and 11, but immunocytochemical assay was posi
in only 53 (55%) of the cases. Jenkins *et al.* [6]
cluded that routine HPV antigen staining of colposc
biopsy specimens is of very limited diagnostic value,
that the technique is best reserved for cases which
colposcopically abnormal but in which no definite hi
logical or cytological abnormality can be found. Mors
al. [7] compared the results of DNA hybridization
cytological findings on 164 Papanicolaou stained cerv
scrapes from 143 women, 124 scrapes were regarde
'normal', with no cytological features suggestive of
vical intra-epithelial neoplasia (CIN), and 40 were f
women with colposcopically and histologically confir
CIN. HPV DNA, predominantly HPV 6 or 16, was pre
in 64 (39%) of the 164 specimens. Cytological char

"When breakthrough bleeding happened to me I was scared, and that's why I called my doctor."

She deserves a

...etter start

TRI·LEVLEN®

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

54%* less breakthrough bleeding* than Ortho-Novum® 7/7/7

Demonstrated in the largest parallel comparative trial of triphasic OCs to date†[1]

*Serious as well as minor side effects have been reported with the use of all oral contraceptives. The physician should remain alert to the earliest symptoms of serious disease and discontinue oral contraceptive therapy when appropriate. Please see full prescribing information, a brief summary of which follows.

†100 women randomly assigned to Tri-Levlen® tablets or Ortho-Novum® 7/7/7; 50 women placed on nonhormonal contraception as a control. Evaluations were made at baseline and once a month for 6 months.

One cycle of Tri-Levlen® tablets therapy provides: ethinyl estradiol–30 mcg/day for 6 days, 40 mcg/day for 5 days and 30 mcg/day for 10 days; levonorgestrel–50 mcg/day for 6 days, 75 mcg/day for 5 days and 125 mcg/day for 10 days. One cycle of Ortho-Novum® 7/7/7 therapy provides: ethinyl estradiol–35 mcg/day for 21 days; norethindrone–500 mcg/day for 7 days, 750 mcg/day for 7 days and 1000 mcg/day for 7 days.

Ortho-Novum® is a registered trademark of Ortho Pharmaceutical Corp.

BERLEX Dedicated to innovation in OB/GYN medicine

TRI-LEVLEN® 28 Levonorgestrel and ethinyl estradiol
TRI-LEVLEN® 21 tablets—Triphasic regimen

BRIEF SUMMARY

Tri-Levlen®—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3,17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage—Tri-Levlen Tablets are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000). the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thrombophlebitis and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to-six-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions:* There have been reports of neuro-ocular lesions, such as optic neuritis or retinal thrombosis, associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring.* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. It is recommended that, for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. In one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, an increased risk was apparent between 6 and 12 months of use.

7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage of patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase in triglycerides and total phospholipids has been observed in patients receiving OCs. Three studies have been performed with the Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets Triphasic Regimen) formulation and no significant alterations in lipid metabolism were noted, with the exception of a slight increase in triglyceride levels in one study. The clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertension may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to normal after discontinuing the drug.

9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of OCs and evaluation of the cause.

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. Irregular breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should be deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical examination and PAP smear being performed. 2. Under the influence of estrogen-progestogen preparations preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OCs: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis—See "Warnings" section for information on the carcinogenic potential of OCs.

Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."

Nursing Mothers—See "Warnings."

Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (see "Warnings"): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.

There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related. Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement and secretion; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—To achieve maximum contraceptive effectiveness, Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours. (If Tri-Levlen is first taken later than the first day of the first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of administration. The possibility of ovulation and conception prior to initiation of medication should be considered.) Any time the patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another method of contraception until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information in package insert. 60611-1 5/86

Clinical Opinion

Missed abortion: Still appropriate terminology?

Gabriella Pridjian, MD, and Atef H. Moawad, MD
Chicago, Illinois

The term *missed abortion* has been in the obstetric literature more than 100 years. With ultrasonographic evaluation of early pregnancy, its textbook definition (death of a fetus without its expulsion for ≥8 weeks) is rarely fulfilled. Yet the term *missed abortion* is still extensively used today with regard to early pregnancy losses. We recommend its abandonment and in its place the use of the following terms: *first trimester intrauterine fetal death, second trimester intrauterine fetal death,* and *anembryonic gestation.* (AM J OBSTET GYNECOL 1989;161:261-2.)

Key words: Missed abortion, anembryonic gestation, nomenclature, ultrasonography

In 1847 Henry Oldham coined the term *missed labor* to describe the situation in which there was death of the ovum without its expulsion in a pregnancy of >28 weeks' gestation. In 1878 J. Mathews Duncun introduced the term *missed abortion* in the *Medical Times and Gazette* to describe a similar situation in which the gestation was <28 weeks.[1] The term *missed labor* has been appropriately lost as obstetrics has developed into a more exact science. However, the term *missed abortion* is still widely used today. *TeLindes' Operative Gynecology* defines missed abortion as a dead fetus retained for ≥8 weeks, or a "prolonged period."[2] *Comprehensive Gynecology* defines missed abortion as fetal death before 20 weeks' gestation without expulsion of any fetal or maternal tissue for ≥8 weeks thereafter.[3] The term was coined in an effort to describe the process of expulsive forces exerted on the conceptus. A missed abortion is a clinical diagnosis made when there are no expulsive forces exerted for a prolonged period of time after the death of the conceptus. The remainder of the spectrum of expulsion are threatened, inevitable, incomplete, and complete abortion.

Before the advent of ultrasonographic techniques, the clinician used lack of growth of the uterus as one of the major clinical signs of death of the fetus, and waited a "prolonged period" to ascertain the diagnosis. The use of the term *missed abortion* today is confusing because ultrasonographic evaluation can assess the status of the conceptus in a much shorter period of time. "Missed" in modern obstetrics implies that the physician could have made the diagnosis earlier, but did not. There should no longer be instances in which missed abortion is diagnosed or pregnancy evaluation is delayed to make the diagnosis. Nor should the term be misused. For example, a patient at 10 weeks' gestation with an ultrasonographic diagnosis of a nonviable fetus cannot be considered to have a missed abortion, by definition, because 8 weeks or a prolonged period has not passed since death of the fetus.

Early pregnancy loss can be a devastating emotional event for a woman and her partner. When possible signs and symptoms of an early miscarriage are evident, evaluaton of the integrity of a first trimester pregnancy should be done expeditiously. Ultrasonography should be performed at the first prenatal visit if the size of the uterus is smaller than dates, if pregnancy has been associated with significant spotting, bleeding, or cramping, or if at ≥8 weeks' gestation no fetal heart tones are heard with Doppler.

It is no longer appropriate to delay diagnosis of a nonviable conceptus until the next visit to determine whether there is growth of the uterus. In our institution, as in others, transvaginal ultrasonography is performed for first trimester pregnancy evaluation if the transabdominal scan is unsatisfactory. Advantages to the transvaginal approach include higher resolution,

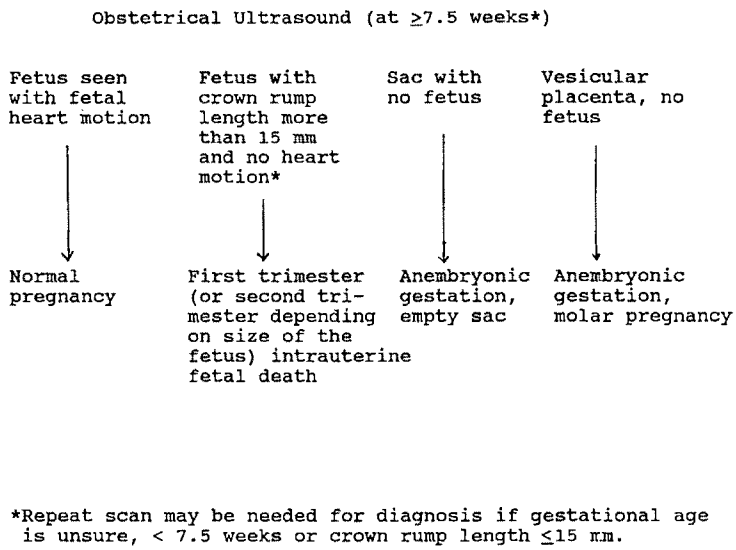

Fig. 1. Nomenclature of early pregnancy status based on transabdominal and, if needed, transvaginal pelvic ultrasonography.

especially in obese patients, and minimal preparation or patient discomfort, as the maternal bladder need not be full. If by ultrasonography, there is no fetal heart activity yet the fetus has a clearly visible body >15 mm, or if dating is excellent (infertility patients) and there is no fetal heart motion at ≥7.5 weeks' gestation, a "first (or second) trimester intrauterine fetal death" is diagnosed.[4] The diagnosis of an "anembryonic gestation, empty sac" or "anembryonic gestation, molar pregnancy" is made when at ≥7.5 weeks there is no fetus[5] (Fig. 1).

When nonviability of a pregnancy is ascertained, a dilatation and curettage procedure should be promptly scheduled. Delay of evacuation of the intrauterine contents may lead not only to hemorrhage and infection during spontaneous abortion, but also to undue anguish by the parents.

Even in instances in which the patient is seen late in pregnancy, the term *missed abortion* is not informative. For example, if a patient at 16 weeks' gestation by accurate last menstrual period is found to have a much smaller uterus on examination and a fetus without heart motion by ultrasonography, biometric measurements should be done to date the fetus in an effort to evaluate when the death occurred. A diagnosis of first trimester or second trimester fetal death may be made on the basis of biometric fetal measurements. If no fetus is found, a diagnosis of anembryonic gestation is much simpler and more descriptive. (Although the conceptus is, by definition, considered an embryo until 8 weeks after fertilization, or 10 weeks after the last menstrual period, for simplicity we have elected to use the term *first-trimester fetal death* to include death of both embryo and fetus in the first trimester.)

The study of the causes of early pregnancy loss may benefit if in the medical record the diagnosis is more precise. It may be that certain chromosomal complements are associated with anembryonic gestations (polyploidy),[6] whereas others are more associated with intrauterine fetal deaths. Maternal factors such as uterine anomalies or fibroids may be more associated with first trimester fetal death, whereas external factors such as infection may be more associated with anembryonic gestations. This information may help us to better counsel patients after they experience a pregnancy loss, especially when the chromosome studies are not available.

In summary, the term *missed abortion* should be abandoned for more accurate descriptions of early fetal losses. We recommend the use of the terms *anembryonic gestation* (empty sac or molar pregnancy), *first-trimester intrauterine fetal death*, or *second trimester intrauterine fetal death*, diagnosed by ultrasonography to be used in its place.

Multidisciplinary team counseling for fetal anomalies

Robert P. Lorenz, MD,[a,b] and Margueritte H. Kuhn, MD[a]
Royal Oak and Detroit, Michigan

Prenatal management of fetal anomalies requires a cooperative effort of the family, obstetrician, ultrasonographer, neonatologist, pediatric subspecialists, nursing staff, geneticists, and social workers. Our approach to these patients is to convene all team members and the family shortly after an anomaly is identified to review the diagnosis, prognosis, plans, and alternatives. Team counseling offers a clear definition of the problem, avoids unnecessary confusion and anxiety for the family, and provides a supportive environment during this family crisis. Our experience with 28 families has been favorable and is described herein. (Am J Obstet Gynecol 1989;161:263-6.)

Key words: Fetal anomalies, prenatal counseling, genetics, perinatal grief

In 1961 Solnit and Stark[1] described the birth of a defective newborn as "the sudden loss of the baby that was expected, and sudden birth of a feared, threatening, anger-evoking child." Davidson[2] described the parental reaction to the live birth of a child with an anomaly as "death of the wished for child." Irvin et al.[3] described the stages of response as shock, denial, sadness and anger, equilibrium, and reorganization.

With recent advances in ultrasonography and prenatal genetic testing, a previous pediatric problem is increasingly becoming the responsibility of the obstetric team. The identification of a fetal anomaly is a devastating family crisis that shatters the usual expectation of a normal pregnancy, birth, and subsequent care of a healthy newborn. The psychologic response to the ultrasonographic finding of a fetal anomaly is similar in some to the birth of a newborn with an anomaly, with elements of shock, denial, anger, and disorientation. When a fetal diagnosis is established remote from delivery, the additional burden of prolonged anticipation and uncertainty combined with the lack of opportunity to directly bond with a visible child requires the full support of the medical team and the extended family.

There have been significant improvements in the ability to identify, intervene, and maximize outcome for the fetus with an anomaly. Management of pregnancies complicated by fetal anomalies is often best treated at tertiary perinatal centers with the resources and the subspecialist teams to assist in these rare problems. In the past such problems were managed by an obstetrician who would request consultation and then transfer care of the fetus to the pediatric team after birth. The family would meet the consultants and pediatric team when the neonatal care began. In cases with complex fetal problems, the family would meet several physicians, nurses, and support personnel, often for the first time during an emergency when urgent decision making was necessary. This "linear" or "sequential" model of one-on-one interactions (Fig. 1) typically may involve the following at different and sequential times: ultrasonography, a visit with the obstetrician, repeat ultrasonography, another visit with the obstetrician (or his/her associate), a consultation with the maternal-fetal medicine specialist, another visit or discussion with the obstetrician, a consultation with the relevant pediatric subspecialist, antepartum fetal testing (e.g., nonstress tests), admission for labor and delivery, care by a neonatologist and nursing team, further consultation and possible surgery in the newborn period, and meetings with social workers, clergy, and others. Meanwhile, the professionals who are involved are reviewing information and discussing differential diagnoses, prognosis, recommendations for testing and management (e.g., timing and mode of delivery). These professional discussions are usually also one-on-one, involving one member (e.g., one obstetrician in a group of four associates) of each group involved. In addition, the patient relays the information from her visits to her partner and often to her other children, her close friends, relatives, and clergy. These family support members have usually not accompanied the patient to most of her visits in the above sequence. Schematically, it is not unusual to have a total of 72 or more one-on-one conversations among interested parties before resolution of the clinical problem (Fig. 1).

As the number of individual conversations increases over the extended time of the patient's workup and consultation process, the probability of unnecessary confusion and anxiety (in addition to the inevitable confusion and anxiety that such a diagnosis carries) rises

dramatically. In addition, the likelihood of full understanding and agreement among all the professionals involved is reduced when one-on-one conversations are the primary mode of planning. Usually someone not involved in these discussions (e.g., nurses, obstetrician, or pediatric surgeon's partner on call) becomes involved in care without full prospective understanding.

Thus the sequential method of management is not the best method to provide a coordinated, supportive, and clear plan to a family facing the crisis of a diagnosis of a fetal anomaly.

Model of multidisciplinary team counseling

Multidisciplinary team counseling for fetal anomalies is a coordinated meeting of caregivers and the family to discuss differential diagnoses, prognosis, and recommendations for care. Principal elements include a conference among the professionals, a conference with the family, and a written report. When a fetal anomaly is first identified (usually by ultrasonography, occasionally by cytogenetic studies), the attending obstetrician is immediately informed and offered the assistance of the team. Within 24 to 48 hours appropriate members are assembled for team counseling. If subsequent diagnostic studies later in pregnancy or patient concern warrants a second counseling session, the same members are reassembled with the family.

Professional conference. Before the conference, a complete review of the prenatal record, genetic history, history, and physical examination by the maternal fetal medicine consultant occurs. Then the family waits in a separate area while the case is presented to the assembled team (see Table I). The ultrasonographic images and reports are presented and discussed. After discussion, a consensus is reached with regard to differential diagnoses, range of prognosis, and recommendations for further testing and therapy (e.g., timing and mode of delivery, possible neonatal surgery). Then the members delegate the topics that each will discuss when the family joins them.

Team meeting with family. Before the meeting, the family is informed of the names and responsibilities of the team members and the purpose of the meeting. Questions are encouraged.

The family joins the conference and sits together near the obstetrician. The obstetrician introduces the other team members and may act as the conference leader. Ultrasonographic results are presented, and each team member reviews the assigned topic and describes his or her role in subsequent care. The patient and her family then can ask questions of anyone present. The family is offered a visit to the neonatal intensive care unit after the conference. The family is given a list of the team members, their departments, and phone numbers for future reference.

All professionals hear everything patient hears
One written plan

examination, ultrasonographic findings, conference participants, discussion, and conclusions related to diagnosis, prognosis, plan, and counseling session is sent to the obstetrician, all members of the team, and all inpatient units (e.g., delivery room, neonatal intensive care unit) where the family will receive care.

Results

During the development of this program (1985 to 1987) there were 104 (0.6%) newborns delivered at William Beaumont Hospital who were admitted to the neonatal intensive care unit with congenital anomalies. Of these newborns, 30 (29%) died in the newborn period. Many patients did not have prenatal diagnosis of the congenital anomaly.

This report describes the approach used for 28 families who had multidisciplinary team counseling for fetal anomalies (Table II). Family participants varied in number from one (one case when the patient came alone) to five. Grandparents of the fetus were the most frequent participants in addition to the partner. Professional participants varied in number from four to nine. The primary obstetrician was on staff at our institution in 23 cases; in 10 cases (43%) he or she was a participant in the conference. Of the five cases referred from other institutions, three had care transferred to our center subsequent to the conference. The combined conferences last an average of 1 hour.

Of the 14 cases diagnosed before 24 weeks' gestation, twelve chose pregnancy termination. Three of the 16 ongoing pregnancies ended in fetal demise, and two in death in the first month of life.

Follow-up included postpartum visits by members of the team, ongoing counseling by the Perinatal Loss Service after a death, and subsequent genetic counseling in many cases. Further follow-up information was received from the primary obstetrician in some cases.

Reactions to this approach from the patients and their families has been overwhelmingly positive. Patients and their families are impressed with the assembled team who are prepared to help their baby. Instead of being intimidated by a large group of strangers, the patients and their families perceived the team conference as reassuring and helpful. In our experience, they seem more prepared for the subsequent birth than patients who underwent sequential management. When the fetal prognosis is poor, the grief process seems to proceed more smoothly when this thorough initial team conference is the beginning. Fewer patients have sought a second opinion since this program began, which we believe reflects a better understanding and acceptance of the problem and plan. When second opinions are requested, the provision of the written record of the multidisciplinary team counseling helps to introduce the second opinion team to what has actually occurred, further reducing the potential for confusion.

Professionals find the conference format educational, and a direct and simple way to analyze a complex problem and decide on a plan. They can all hear what the family hears, and observe their reactions and questions. It saves time for everyone because patients are less likely to initiate extra telephone calls and visits to review information. The written report is a tremendous aid in subsequent management and counseling.

Comment

Sequential counseling versus multidisciplinary team counseling for fetal anomalies is compared in Table III. The latter offers a more rapid response and formulation of a consensus plan, which is most helpful to the family. It removes the family perception of differences of opinion (or openly clarifies what the differences are) among the professionals who will be involved in perinatal care. It provides an opportunity for the family to meet in advance the people who will be caring for their child, before critical decision making is necessary. It is a useful eductional tool for all members of the team and provides updates on all aspects of an approach to fetal anomalies. It provides a supportive group of

knowledgeable family members and professionals to help the patient and her partner in a time of crisis. Sixty-one percent of the cases described ended in pregnancy termination, fetal death, or neonatal death. In these cases, the team management conference becomes a central element in management of perinatal grief. The grief process is supported by the presence of well-informed family members and the professional team.

Principles of counseling families with a newborn with an anomaly[3, 4] and with a perinatal loss[5-7] have been previously addressed. Families should be openly counseled together soon after the diagnosis, in a setting that is private and unhurried. professionals involved include a perinatologist and a chaplain or social worker[8] for perinatal loss and the pediatrician and a physician in training[3] for the newborn with a congenital anomaly. For the family of a fetus with a fetal anomaly, we believe a larger group for the initial management conference is more beneficial. Subsequent grief counseling after a death is assigned to one member of the initial counseling team.

Ideally, the primary obstetrician is involved in the counseling session. As the person chosen by the patient to assist her with her pregnancy and birth, he or she represents a trusted and familiar figure in a time of uncertainty, fear, and axiety. In the first few years of this program, the obstetrician was able to and chose to participate in 43% of the conferences. Participation increased in the later years as obstetricians understood the team conference and its benefits. In many cases, schedules did not permit participation of all members of the team, or the obstetrician, in these hastily assembled conferences. It is understandable that some obstetricians chose not to participate in a setting of an unfamiliar fetal problem and in a format of a group session. Such a format may be uncomfortable for some physicians who have been trained and are more comfortable in a one-on-one patient interaction in an office setting. On the positive side, obstetricians who have participated are enthusiastic about the format, and many of them now utilize it and participate when clinical circumstances warrant this approach.

Multidisciplinary team counseling requires effort on the part of the members, flexibility in making schedule changes to participate, and time. In our experience, the effort is worthwhile and results in better coordination of care and more effective support of the family. We believe this is truly a "better mousetrap," and encourage others to adapt it to their management of fetal anomalies, as well as pursue formal studies of its effectiveness compared with other approaches to fetal anomaly counseling and management.

Breast disease programs in obstetrics and gynecology: A plea for training in mammography

Norbert Gleicher, MD
Chicago, Illinois

Obstetrics and gynecology residency programs have started to integrate structured breast disease teaching programs into the curricula. I suggest that mammography training should be the cornerstone of programs on the diagnosis of breast diseases. The implementation of such a program into a teaching department is described in an attempt to facilitate similar efforts elsewhere. (AM J OBSTET GYNECOL 1989;161:267-70.)

Key words: Mammography, breast disease, medical education

Recommendations by a variety of professional bodies have mandated the establishment of teaching programs for the diagnosis of breast diseases within departments of obstetrics and gynecology. Although this mandate was primarily directed at residents within approved obstetrics and gynecology residency programs and could have been fulfilled through elective periods and other forms of cooperation outside the departments of obstetrics and gynecology, our department decided to develop its own intramural program. The following is a description of the program development process through its inception, planning, and implementation phases. From the subsequent comments it will be apparent that my strong preference lies with programs within obstetrics and gynecology departments and not in efforts outside the department. It is hoped that the subsequent pages will convince others of this viewpoint and will help to facilitate the necessary implementation process elsewhere.

Historical perspective

Little doubt can exist that the female breast is a reproductive organ. In that function it represents the only reproductive organ outside the treatment perview of our specialty. Except for some minor geographic exceptions, diagnostic as well as surgical management of breast disease has in this country become exclusively the territorial property of radiologists and surgeons. This is despite the fact that gynecologists more than any other medical specialty serve as primary care providers to women, perform breast examinations, and diagnose breast disease, inclusive of carcinoma.

Although it is most frequently the gynecologist who first faces breast pathology, it is usually the radiologist who performs diagnostic procedures of mammography and breast ultrasonography and the surgeon who obtains biopsy specimens and operates when required. The patient by that time has seen three physicians, has made three appointments, and has waited in three waiting rooms. She also, in a way, has been abandoned by the primary physician responsible for her reproductive health, her gynecologist.

The concept of preventive screening was invented in our specialty when Papanicolaou developed the Papanicolaou smear in an attempt to decrease the incidence of invasive carcinoma of the cervix.[1] Large scale Papanicolaou smear screening has reduced the annual incidence of newly diagnosed invasive carcinomas of the cervix by 50%.[2] Quite correctly, the American College of Obstetricians and Gynecologists objected to earlier recommendations by the American Cancer Society, which had suggested that low-risk patients did not require an annual Papanicolaou smear.[3] A very strong argument for annual Papanicolaou smears was the concomitant physical examination that, it is hoped, is inclusive of a breast examination.

At present approximately 110,000 new cases of carcinoma of the breast occur annually in the United States. Approximately 37,000 women die annually from the disease.[4] European studies have conclusively demonstrated that routine mammography screening can reduce mortality from breast cancer ≤60%.[5,6] To the gynecologist this should not come as a surprise. After all, we invented the concept of precancerous lesions.[1] As with most other tumors, survival after breast cancer correlates closely with tumor size at time of diagnosis.[7] Because mammography can detect

From the Department of Obstetrics and Gynecology, Mount Sinai Hospital Medical Center, and Rush Medical College.

breast cancer of nonpalpable size, mammography can and should be seen as the "Papanicolaou smear" of the breast. This concept has been recognized and has been the basis for broadly based screening recommendations formulated by various medical organizations and endorsed by the American College of Obstetricians and Gynecologists as early as 1979.[8]

Why the gynecologist?

If one accepts the notion of wide-scale mammography screening, then one has to address practicality, efficiency, and costs of such an effort. All three of these issues point toward the gynecologist. Because the gynecologist is usually the only health care provider women see on a regular (i.e., annual) basis, mammography screening should take place when and where her other screening concerns (Papanicolaou smear, pelvic exam, breast exam) are addressed. Such an approach is not only logical, but also convenient for the patient and is the most cost-effective approach. If all regularly required screening processes can be combined into one visit, costs have to compare favorably with all alternatives. Such an approach will return the primary care responsibility for breast care to the gynecologist and thus reestablish our specialty as the exclusive providers of female reproductive health care. An argument can be made that the quality of breast care in this country often lags behind European countries, because no specialty has assumed primary responsibility for the female breast. By the assumption of this responsibility, our specialty can potentially save more lives than with any other presently recommended screening program.

If we accept responsibility for the diagnosis and proper care of female breast disease, then one has to conclude that we have to learn mammography. An analogy to the performance of pelvic ultrasonography immediately comes to mind. Initially in the perview of radiologists, the logic of clinical practice has shifted pelvic ultrasonography increasingly toward the gynecologist. As the pelvic mass on bimanual exam requires ultrasonographic follow-up, so does the breast mass radiographically (and at times by ultrasonography).

Residency programs are now required to provide curricula in ultrasonography. Both general and subspecialty boards expect certain levels of ultrasonography expertise from candidates. If the diagnosis of breast disease is to be taught to our house staff, then mammography interpretation needs to be taught immediately after instruction of proper breast examination and long before breast biopsy and other surgical issues become relevant.

Since the diagnosis of breast disease has entered our residency program curricula, faculty have to teach the topic. In our department this was seen as an opportunity to integrate mammography into a newly established breast disease program that included a dedicated mammography unit.

Program development

Establishment of a departmental breast program was clearly initiated by the newly established requirements to teach the pathophysiology and diagnosis of breast disease to our house staff. In an attempt to develop a rational and a feasable program approach for our institution, we concluded that we had to proceed through the following developmental steps:

1. Didactic education of faculty and house staff. Because none of our faculty had the expertise to provide the required information, a lecture series with outside speakers was scheduled over an approximately 6-month period.

2. Program emphasis on breast examination in the departmental outpatient clinic. Under faculty supervision, the house staff was closely inspected in the performance of breast examinations. Each house officer received a "breast examination card" on which attending physicians had to certify that they witnessed 20 correctly performed breast examinations.

3. Establishment of a dedicated mammography unit for breast cancer screening. Because the institutional political situation did not allow the placement of this unit within the hospital confines, the unit (General Electric Mammoview Mammography System, Naperville, Illinois) was placed in the private practice facility of the geographic full-time faculty group. The already available ultrasonography unit at that site (General Electric RT 3600 with 7.5 linear transducer, Naperville, Illinois) was upgraded to allow the performance of breast ultrasonography when needed in support of mammography.

4. Faculty training in mammography and breast ultrasonography. Faculty were sent outside the department for training in mammography and breast ultrasonography. All faculty members who wished to receive "certification" to read mammograms had to attend both a basic and advanced mammography course offered by the widely respected mammographer L. Tabar. This requirement was not only established because of the noted excellence of these courses, but also to assure uniformity of the reading process.

The introduction of mammography into the department came 6 years after the establishment of processes that introduced obstetric and gynecologic ultrasonography to faculty and house staff. Then and today, selected faculty members underwent training first. Once their level of competence reached satisfactory levels, senior residents were integrated into the scan-

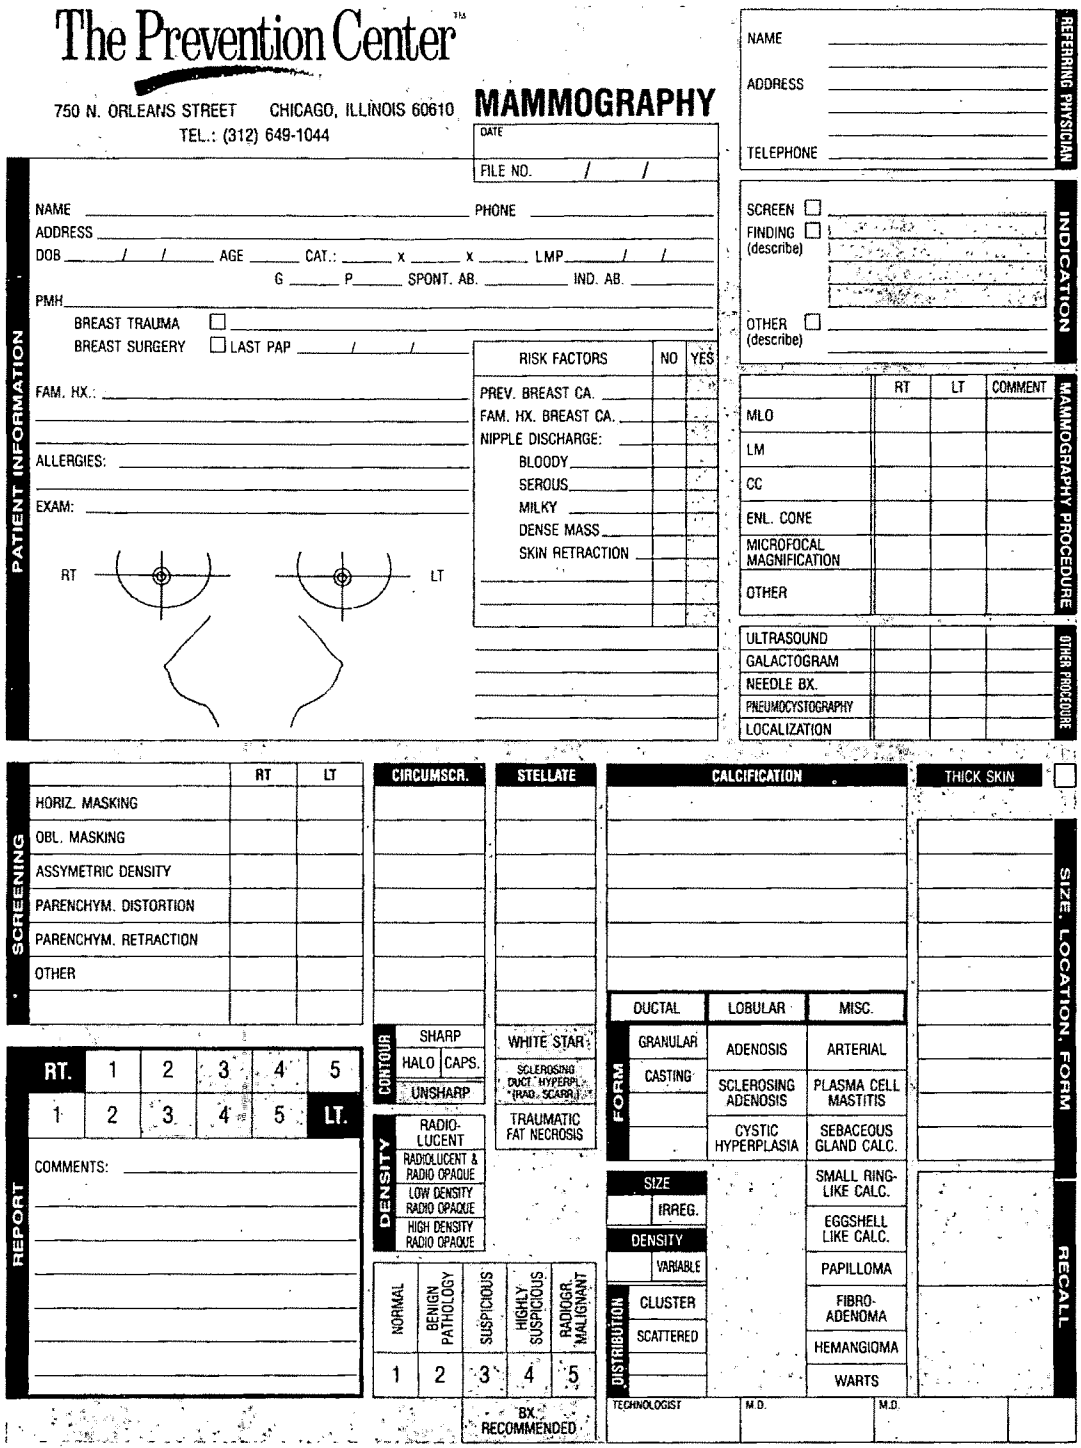

Fig. 1. Mammography reading and reporting form was developed to apply standard mammography reading techniques to mammography reading process in department. Stepwise approach to mammography is forced on reading physician because each reading step has to be indicated separately. Final result of reading process is detailed description of each finding. Note that all findings indicative of potential malignancy and all high-risk factors in patient's history are highlighted in red *(shaded area)*. Each breast is classified in classes I to V as indicated. Classes III to V indicate biopsy recommendation.

ning process. Over a 4-year period practical hands-on education reached the first-year residents. Over the past 2 years all house staff have been actively involved in the routine performance of obstetric as well as gynecologic ultrasonography in the department. In 1987 approximately 90% of all departmental scans were performed by residents with very satisfactory sensitivity and specificity.

Although faculty training in mammography was not completed until July 1988, the education process for selected senior residents began in March 1988 when the mammography unit opened. It was expected the unit would perform 20 to 25 breast examinations per day by July 1988. Mammography reading skills are projected to reach first-year residents by 1992.

To emphasize mammography as the "Papanicolaou smear" of the breast we developed a mammography reading report sheet that follows standard reading recommendations by L. Tabar but classifies each breast in accordance with Papanicolaou smear classifications into five classes (Fig. 1). This results in a reading process with a clear recommendation of whether to obtain a biopsy specimen.

Also a recommendation of L. Tabar,[9] we decided to double-read each mammography study. This provided an opportunity to collaborate with our radiology colleagues who double-read each film. Although we believed strongly in the placement of the breast diagnosis program within the obstetrics and gynecology department, we also believed that professional teamwork between medical disciplines was essential if the best possible care was to be provided to patients. Double-reading gave the opportunity of collaboration with the radiology department. The performance of breast surgery established this opportunity for collaboration with the surgery department. By the association of one general surgeon with special interest in breast surgery with the program, we provided the necessary surgical expertise to the patient, and to the teaching program at the same time. Although three departments are thus involved in the breast program, its structure is clearly different from any other program of which we are aware. Not only is a clear primary responsibility established, but it is established within our specialty. We believe this not only improves our teaching process for breast disease but, more importantly, has greatly improved medical care for our patient population.

Intrauterine growth retardation: Standards for diagnosis

Robert L. Goldenberg, MD, Gary R. Cutter, PhD, Howard J. Hoffman, MA, Judith M. Foster, MPH, Kathleen G. Nelson, MD, and John C. Hauth, MD
Birmingham, Alabama

An intrauterine growth-retarded infant is commonly defined as one weighing less than the 10th percentile in birth weight for its gestational age. However, because there is no standard population from which to derive these percentiles, the birth weights that serve as the cutoff point in various published studies may differ by several hundred grams at any gestational age. For this reason, we examined the studies from which the currently used 10th-percentile standards are derived to determine which factors may be responsible for the variation. In addition to obvious differences in the populations and geographic areas on which they were based, studies differed in how gestational age was determined, whether the gestational age was "rounded" or given in completed weeks, which types of infants were excluded, whether the studies were hospital or population based, and whether they were controlled for sex of the infant and race and parity of the mother. These differences in study methodology may be as or more important than the population differences in defining the 10th percentile cutoffs. A single national standard for intrauterine growth retardation would allow comparison between studies of risk factors, diagnostic tests, management, and long-term follow-up status of fetuses and infants with intrauterine growth retardation. (Am J Obstet Gynecol 1989;161:271-7.)

Key words: Intrauterine growth retardation, small for gestational age, low birth weight

Fetal growth insufficient for length of gestation is associated with an increased risk of perinatal mortality and morbidity.[1] Common to each investigation of infants with intrauterine growth retardation (IUGR) is a decision about the criteria that will define the condition, usually a birth weight below an arbitrarily chosen point at each gestational age. These cutoff points have included the 3rd[2] and 5th percentile of birth weight,[3] 2 SD below the mean,[4,5] and the more commonly used 10th percentile.[6] Since race and parity of the mother and the sex of the infant influence birth weight, standards specific for these factors also have been published.[7-9] It is obvious that use of different birth weight percentiles, or correction of the standard for race, parity, and sex of the infant have a major effect on the birth weights that define IUGR. However, there are substantial differences in the various published standards that are defined by the 10th percentile alone.

Because infants of certain weights will be diagnosed as having IUGR in some studies but not others, many of the IUGR-related risk factor and infant outcome studies are not comparable, which often leads to conflicting results. Our review, comparing the 10th percentile birth weights in various reports, was undertaken to better understand the populations from which the standards were developed and the methods used to determine the 10th percentile values ultimately published.

Methods

The studies reviewed were selected from those published in the English literature since 1963 that presented in tabular form values for the 10th percentile of birth weight for gestational age. These studies were characterized by location, source of data, the method used to define gestational age, exclusions, sample size, patient characteristics, and the methods used to determine the 10th percentile values. In addition, to illustrate the differences for selected gestational ages, the actual 10th percentile values from each of the studies are presented. When available, the 10th percentiles for boys and girls, black and white infants, and primiparous and multiparous women also are presented.

Results

The 10th percentile birth weights at several gestational ages from the various studies are presented in Table I. When available, the 10th percentiles for male and female infants, black and white infants, and infants of parous and nonparous mothers are presented separately. In addition, for each group of studies defined by the same sex, or inclusion of both sexes, the maximum difference in 10th percentile birth weight be-

tween the standards at each gestational age studied is presented. There are large differences in 10th percentile cutoff points between the various standards, with the differences >500 gm at some gestational ages.

We hope to explain some of the reasons for this variation (Table II) by discussing the methods used to construct each set of standards.

The most widely used birth weight standards are

those of Lubchenco et al.[6] from Denver. This study population consisted of 5635 live-born white infants. Exclusions consisted of infants with anencephaly, hydrocephalus, hydrops fetalis, and maternal diabetes as well as all nonwhite infants. In addition, 55 infants thought to be too large for gestational age at delivery also were excluded. Gestational age was calculated from the first day of the last menstrual period (LMP) and was presented in completed weeks. As shown in Table I, these standards tend to be lower than the others, especially at later gestational ages. This difference has been thought, at least partially, to be a result of the high altitude of the Denver area. It should be noted that the very small number of infants studied at many of the gestational ages make the confidence limits of the cutoff points at many gestational ages very large.

Brenner et al.[10] analyzed data from 30,772 deliveries at 21 to 44 weeks' gestational age in Cleveland. The population was 53% white and 47% nonwhite (98% black). Data were analyzed from singleton births from pregnancies not complicated by preeclampsia, breech presentation, erythroblastosis, diabetes mellitus, or congenital abnormalities. Gestational age was calculated and rounded to the nearest week from the first day of the last normal menstrual period. Correction factors for parity, race, and infant sex were calculated and presented, but 10th percentile measurements for these subgroups were not presented.

Miller and Merritt[8] analyzed extensive anthropometric data on a mixed population of 6000 black and white infants born at The Univesity of Kansas Medical Center from 1973 to 1978. Their intention was not to do a population-based study but instead to develop normal standards for fetal growth in a population of surviving infants devoid of risk factors for IUGR. From their original population of 6000, they presented data by parity and sex for 1200 term white infants and by sex for 473 term black infants. For an infant to be included in the study, the gestational age as determined by LMP, ultrasonography, maternal clinical measurements, and a newborn examination had to be in agreement. The 10th percentile standards in this study were considerably higher than those in other published studies (Table I).

The fetal growth standards developed by Kloosterman[7] were also reviewed. These standards were constructed by investigation of 80,000 mostly white pregnancies in Amsterdam between 1931 and 1965. Eight percent of those cases in which the gestational age was unknown or uncertain, stillbirths with maceration, and multiple births were excluded. The LMP was used to determine gestational age in completed weeks. The mean and various percentile weights for each gestational age were determined by use of the birth weight. The authors considered the differential effect of sex and parity (primiparous and multiparous women) on birth weight and constructed curves for each of the four combinations of sex and parity.

Milner and Richards[11] used data from England and Wales to construct fetal growth curves. They chose a random sample of 9.7% of all births at the National Health Service Hospitals from 1967 to 1971. After exclusions, this sample represented 8.5% of all births at these hospitals and consisted of 271,519 births. Birth weights were analyzed at each gestational age by sex of the infant and maternal parity.

Data from the Collaborative Perinatal Project of the National Institute of Neurological and Communicative Disorders and Stroke were analyzed by Naeye and Dixon.[12] These data were collected prospectively from 12 hospitals in the United States between 1959 and 1966. The study population consisted of 48,239 single-born neonates who were alive and well at 1 year of age. The racial distribution consisted of 46% black, 46% white, and 8% other. Gestational age was based only on the LMP; the reported gestational age was rounded to the nearest week. Birth weights of survivors only were plotted by gestational age. Cases were found to cluster at birth weight intervals consistent with a bimodal distribution similar to that described by Milner and Richards.[11] The lowest weight cluster was chosen at each gestational age.

Birth weight for gestational age data from The Collaborative Perinatal Project were also reported by Hardy et al.[13] In this report, in contrast to that of Naeye and Dixon,[12] 10th percentile values were reported by race and sex. The population consisted of 18,481 white and 19,504 black singleton live-born infants with known birth weight. The data presented were reported as collected. There were no adjustments or exclusions. For this study, gestational age was based on the LMP only and was rounded to the nearest week.

Babson et al.[14] reviewed 39,895 deliveries at two maternity hospitals in Portland, Oregon, from 1959 through 1966. The mothers were primarily of Northern European descent, lived near sea level, and received private prenatal care. The gestational age, rounded to the nearest week, was generally calculated from the first day of the LMP. However, in determining the gestational age at delivery, clinical data were at times taken into consideration. Also all fetal deaths, multiple births, and nonwhite infants were excluded from analysis.

In a recently published monograph, Carr-Hill and Pritchard[15] present an extensive discussion of the development of birth weight standards. The population for their analysis consisted of 17,528 singleton births in Aberdeen from 1975 to 1980. All stillbirths and births from multiple pregnancies were excluded. Gestational age was recorded in completed weeks since the first day of the LMP, and only women with certain LMPs were included. They presented their 10th percentile data divided by sex of the infant and parity of the

mother (a total four standards) from 32 to 42 weeks' gestational age.

The 10th percentiles presented from The University of Alabama are calculated from a hospital-based data set of 4497 live births from women with a "sure" LMP (unpublished observations). Approximately 70% of the mothers were black. No exclusions were made for congenital anomalies. Gestational age at delivery was calculated from a prenatally determined estimated date of confinement by not only the "sure" last menstrual period but also other clinical indicators of gestational age. The authors found that use of the obstetrician's best prenatal estimate of gestational age resulted in a greater percentage of the births at 39 and 40 weeks and less variability of birth weight at each gestational age than in the "sure" LMP data derived from the same population. These corrections also resulted in relatively higher 10th percentiles at later gestational ages and lower 10th percentiles at the earlier gestational ages.

All of the previously described studies utilized hospital data. It has been suggested that 10th percentiles of birth weight at each gestational age may differ significantly between hospital data and population-based data. Therefore it was also of interest to examine population-based studies for comparative purposes.

One such study was by Thomson et al.[16] Data were collected from 52,004 legitimate, singleton births in Aberdeen from 1948 to 1964. Infants with congenital anomalies and macerated stillbirths were excluded from the study. Gestational age was determined from the first day of the last normal menstrual period and was classified as certain, uncertain, or unknown. In the uncertain group, clinical information combined with the LMP was used to define the gestational age. Those with unknown gestational ages, comprising about 10% of all births, were excluded. Gestational age data were reported in completed weeks. The data were analyzed, and percentiles of fetal weight were constructed by parity and sex.

Hoffman et al.[9] (1968) used a 50% sample of all live

CPP, Collaborative Perinatal Project; *NCHS,* National Center for Health Statistics.
* Unpublished observations.

U.S. resident births in 36 states and the District of Columbia in which the first day of the LMP was reported on the birth certificate. Data from 1,164,871 births were analyzed. Exclusions included births to women not reporting an LMP, births to women in states that did not record LMP on the birth certificate, multiple births, births to women not recorded as white or black, and births less than 20 weeks' gestational age. In this paper, birth weight for gestational age percentiles, including the 10th percentiles, were presented for four groups separately by race and sex of the infant.

Williams et al.[17] conducted a large population-based study in California with matched birth and death certificate data. As in the article by Hoffman et al.,[9] the large sample size (2,288,806 births) allowed for evaluation of confounding variables such as sex, race, and plurality. Infants with congenital anomalies or antenatal complications were not excluded from this study. Gestational age was calculated from date of birth and date of last normal menstrual period. The 10th percentiles of birth weight were calculated in weekly intervals. This study attempted to address the problem of inaccuracies in gestational age that result in skewed distributions of birth weight. The greatest effect was thought to be on the 90th percentile because of "heavy" infants who were mistakenly given low gestational ages, whereas the 10th percentile was believed to be only slightly affected.

Comment

One of the major difficulties in understanding the literature devoted to IUGR is determining which infants have been included in any particular study. Since IUGR is most commonly defined as a birth weight < the 10th percentile at each gestational age, the population from which the standards are derived to define the 10th percentile is of major importance. However, in study after study the investigators appear to choose standards with little concerns for the relationship of that "standard population" to their own. In addition,

infants that are classified as having IUGR by one standard are not by other standards. Therefore studies that evaluate risk factors for IUGR, the use of various tests for IUGR, and follow-up studies of infants with IUGR are often not easily compared, at least in part, because the birth weights used to define the condition at any gestational age are not similar.

This study clearly shows that the 10th percentile birth weights at each gestational age from various published standards differ substantially, even occasionally by >500 gm. However, in many cases despite the apparent large differences, especially at the early and late gestational ages, because of very small numbers, the 10th percentiles may not even be statistically different[6,8] (unpublished observations). When real differences do exist, it would appear that the racial composition and socioeconomic status of the population, the height of the geographic area above sea level, and which infants were excluded may influence the birth weight distribution. Equally as important, however, appears to be the method used to determine the gestational age. For example, a number of studies examined infants' birth weights retrospectively and discarded some cases because the gestational ages were not compatible with their birth weights, or because mathematic modeling made it unlikely that certain groups of infants were of a gestational age in agreement with the LMP.[6,8,14] Furethermore, some studies rounded the gestational age,[10,12-14] whereas other authors presented the data in completed weeks.[6,11] Most used the LMP alone to determine the gestational age at delivery, but clinical data were used to influence the gestational age in at least three studies[8,14] (unpublished observations). In summary, there are so many methodologic differences between studies that differences that do appear to exist in the 10th percentiles between populations may possibly be attributed solely to methodologic differences. Certainly there has been no standard method for determining the birth weight for gestational age "standards."

The following discussion addresses some of the issues that must be settled in selecting a population and determining the methodology if a uniform set of standards for the diagnosis of IUGR is to be developed.

First, the issue of whether to use separate 10th percentile standards established for race, sex, and parity for diagnosing IUGR is a difficult one to resolve. For example, although it is apparent that black infants generally weigh less than white infants, and their 10th percentile cutoff points are less, it is not clear that this difference is solely a result of less genetic potential for growth. Instead, black infants have more risk factors for low birth weight,[18] including lower maternal socioeconomic status and more instances of maternal hypertension. Therefore the issue regarding race and potential for growth does not appear resolvable. However, since most U.S. studies of IUGR involve racially mixed populations, there are advantages to having a single standard that is based on a racially mixed U.S. population. However, in other cases the use of race-specific standards may be appropriate. These standards should be developed from the same population.

Male newborns weigh more than females, and the 10th percentile cutoff is higher for males than females. Since there do not appear to be more risk factors in mothers who are delivered of male infants[18] and since female infants do not appear to be at a disadvantage because of their lower weight, it seems reasonable to use sex-specific standards. Otherwise, infants classified as having IUGR will include a disproportionate number of apparently healthy female infants.

Infants born to parous women are generally heavier than those born to nulliparous women; their 10th percentile cutoffs are heavier as well. Currently it is not clear whether primiparous women have more or less risk factors for IUGR (i.e., more toxemia but possibly less chronic hypertension, a lower prepregnancy weight, etc.) or if their infants fare less well. However, it would appear that the genetic potential for fetal growth is equivalent in multiparous and primiparous pregnancies, but that there are factors related to the primiparous state itself that tend to constrict growth. In view of the likelihood that fetuses born to primiparous mothers have more growth potential than they generally attain, and since most studies of IUGR are performed on populations of mixed parity, in most studies we would recommend the use of a single standard based on a population of mixed parity for practical purposes.

There is reasonable evidence that infants born to mothers residing at high altitudes have smaller babies,[6,19] and some have recommended using standards based on geographic location. Because there is no reason to believe that these "high altitude" babies have less genetic potential to grow than other babies, it seems reasonable to conclude that the high altitude is a growth retardant and should be considered a risk factor for IUGR. Since it is not reasonable to base standards for diagnosing IUGR on a population at high risk for this condition, we would recommend that the standards be derived from a population whose fetal growth is not influenced by geographic constraints.

Despite the fact that nearly all standards are based on LMP data alone, virtually all studies involving infants with IUGR are now reported with gestational ages calculated from the LMP but modified by clinical data and ultrasonography. It makes little sense to use gestational age standards for diagnosing IUGR based on LMP alone when the infant's gestational age will be

determined differently for most studies. Therefore we recommend that for the derivation of standard 10th percentiles, the gestational ages should be LMP-based but should be confirmed by early clincal and ultrasonographic data.

When establishing standards, the issue of which infants to exclude for medical or risk factor indications is also difficult to resolve. Some authors, especially those using vital statistics data, exclude no cases.[9, 17] Others exclude some infants with congenital anomalies but include others.[6] Most, but not all, exclude multiple births. Miller and Merritt[8] excluded not only abnormal infants, perinatal deaths, and multiple births, but also those with any known risk factor for IUGR such as smoking. Although there is clearly no one "right" choice as to which infants should be excluded in developing a percentile standard for IUGR, the use of a consistent method is important if studies on IUGR in various populations are to be compared. For consistency and to eliminate the idiosyncratic nature of exclusions or inclusions in so many studies, one obvious solution in developing standards would be to include all live-born infants born to the population evaluated.

In conclusion, we strongly believe that there should be a single, clearly defined U.S. population from which the percentiles for defining IUGR are derived, and that unless there are specific reasons to the contrary, studies on IUGR performed in the U.S. should use these standards. Although there is general consensus that the 10th percentile should be used for most studies, those who want to evaluate greater or lesser degrees of growth retardation may want to use the 3rd, 5th, 15th, or 25th percentile. These percentiles should be derived from the same standard population for consistency. Similarly, for researchers interested in using race- or parity-specific values, the race- or parity-specific percentile standards should be derived from this standard population.

The characteristics of the specific population on which the standards should be based are subject for debate. For example, we believe that the standards should be derived from a hypothetical population that is representative of U.S. pregnancies on the basis of demography, risk factors, and perinatal outcome. Obviously, there is room for discussion (and disagreement among the authors) about other specific decisions regarding sex, race, parity, multiple birth, certain congenital anomalies, etc. In addition, there are also important decisions to be made, with regard to method, such as how the gestational age should be determined and/or confirmed. Nevertheless, we believe that after appropriate discussion and compromise, representatives from appropriate decision-making groups should be able to reach agreement on a standard population.

Much of the confusion that presently surrounds IUGR would be eliminated if The American College of Obstetricians and Gynecologists, The American Academy of Pediatrics, The Society of Perinatal Obstetricians, and the appropriate committees of the National Institutes of Health, The Centers for Disease Control, and The National Center for Health Statistics could together endorse the same national standard, and U.S. researchers would use this single common standard in their studies.

Anal and perianal abnormalities in prepubertal victims of sexual abuse

David Muram, MD
Memphis, Tennessee

We describe anal and perianal findings in 310 prepubertal children who were determined to be victims of sexual abuse; 206 (66%) had perinea that appeared normal. Abnormal findings were present in 104 children (34%): anal gapping in 61 children; skin tags in 44; rectal tears in 33; sphincter tears in 15; human papillomavirus lesions in 4; perineal scarring in 2; and bite marks in 1. Normal-appearing perianal and anal regions were noted in 150 of 175 children (85%) who denied anal assault, and in 11 of 70 (16%) who described such assault. In comparison, anal and perianal abnormalities were observed in 59 of the 70 children (84%) who gave a clear history of anal assault, but in only 25 of 175 (15%) who denied such abuse. Failure to document perianal abnormalities in almost two thirds of the patients demonstrates the limitations of the medical evaluation in validating allegations of sexual abuse. (Am J Obstet Gynecol 1989;161:278-81.)

Key words: Children, sexual abuse, anus, perianal abnormalities

Child sexual abuse is a common and serious problem that affects children regardless of their age, sex, socioeconomic class, or geographic location.[1, 2] Anal assaults comprise a significant proportion of these attacks.[2, 3] Although genital injuries are often recognized as possible signs of abuse,[4, 5] anal and perianal injuries are sometimes dismissed by physicians as being associated with common bowel disorders (e.g., constipation or diarrhea).[6-8] This article describes the anal and perianal findings in a large group of prepubertal children who were determined to be victims of sexual abuse by their history and by the local investigative teams of Child Protective Services, a branch of the Tennessee Department of Human Services.

Material and methods

The demographics of Shelby County, Tennessee, and the referral patterns to the Pediatric Gynecology Clinic have been described in previous articles.[2, 4] Between Jan. 1, 1986, and April 30, 1988, the Tennessee Department of Human Services referred 310 prepubertal children between the ages of 1 and 10 (163 white and 147 black; 41 boys and 269 girls) who were determined by their history and the ensuing investigation by the Tennessee Department of Human Services to be victims of sexual abuse. All patients in this study group were examined in an office setting by the same examiner; this allowed consistent and uniform data collection. All children in the study group were prepubertal, as confirmed by the medical examination. For the evaluation of the perianal region, the children were placed in one of three positions: frog-legged supine, "knee-chest" position, or across the parent's lap, simulating the "knee-chest" position. The glutei were separated so that the anus and perianal area could be fully inspected. In addition to the unaided examination, the perianal area was also inspected either through a Zeiss or Codman colposcope under ×16 magnification. The area was inspected under regular illumination and through a green filter that better demonstrates vascular patterns. No solutions or dyes were applied to enhance visualization. The examiner recorded changes in skin color, texture, and all other lesions or abnormalities.

The various perianal abnormalities observed in the study population were defined as follows:

1. Inflammation—redness, swelling, tenderness of the perianal tissues

From the Section of Pediatric Gynecology, Department of Obstetrics and Gynecology, University of Tennessee.

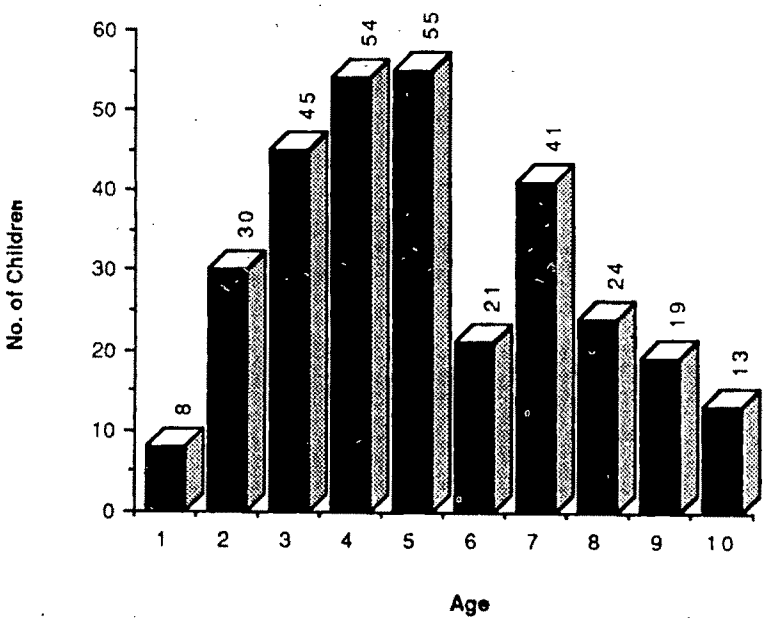

Fig. 1. Age distribution of the study group.

2. Rash—perianal skin eruption
3. Ulceration—loss of the superficial layer of the skin or mucosal surface
4. Skin tag—excess of perianal skin raised near the mucocutaneous junction that could not be eliminated by stretching nearby tissues
5. Fissure—a deep linear cleft or ulcer at the mucocutaneous line of the anus
6. Anal gapping—relaxation of the anal sphincter to a diameter ≥1 cm when the glutei were separated

The genital abnormalities were classified into one of three categories, as have been previously described in detail[4]:

1. *Category 1.* Normal-appearing genitalia
2. *Category 2.* Nonspecific findings—abnormalities of the genitalia that could have been caused by sexual abuse but also are often observed in patients who are not victims of sexual abuse (e.g., inflammation and scratching)
3. *Category 3.* Specific findings—the presence of one or more abnormalities strongly suggesting sexual abuse.

The allegations

Many children described a complex abusive situation in which repetitive sexual acts were performed over a variable time period. In some instances, it was difficult to evaluate the progression of the abusive relationship, the time span over which the abuse occurred, and the number of attacks. In 175 of the 310 children (56%), the abusive relationship affected other areas of the victim's body and did not involve the anal area (e.g., oral–genital contact). In another 65 children (21%), it was impossible to ascertain from the child's description if anal assault occurred. In only 70 instances (23%) did victims clearly describe an assault involving the anal area. Some were combined with genital assault (n = 47), anal coitus alone (n = 18), or digital manipulation of the anal area (n = 5).

Results

Age distribution. The mean age of the children in the study group was 5.2 years (range, 1 to 10 years). A difference in age distribution by racial group was noted; black children were older (mean age, 5.7 years) than white children (mean age, 4.8 years). The age distribution for the entire study group is shown in Fig. 1.

Findings. Two hundred and six children (66%) had normal-appearing perinea. Abnormal findings were present in 104 children (34%): anal gapping was found in 61 children, either as an isolated finding (n = 12), or in association with other findings. Skin tags were found in 44, either as an isolated finding (n = 21), or in association with other findings. Rectal tears were seen either as an isolated finding (n = 12), or in combination with other findings (n = 21). Sphincter tears were observed as an isolated finding (n = 1), or with anal gapping, rectal tears, or skin tags (n = 14). In four patients, perineal human papillomavirus lesions were seen; in two patients, perineal scarring was noted in association with perianal skin tags. One girl had bite marks on the perianal area. The findings are listed in Table I.

Table I. Perianal and anal findings in prepubertal children ($N = 310$) who were victims of sexual abuse

	No. of patients
No abnormalities	206 (66%)
Skin tags	21
Anal gapping, rectal tears	18
Anal gapping	12
Rectal tears	12
Anal gapping, rectal tears, skin tags	7
Anal gapping, skin tags	6
Perianal warts	4
Skin tags, rectal tears	3
Rectal tears, sphincter tears	3
Anal gapping, sphincter tears, rectal tears, skin tags	3
Anal gapping, sphincter tears	3
Skin tags, perineal scarring	2
Anal gapping, sphincter tears, rectal tears	2
Redness, irritation	1
Redness, irritation, rectal tears	1
Sphincter tears	1
Sphincter tears, skin tags	1
Skin tags, redness, irritation	1
Bite marks	1
Anal gapping, sphincter tears, rectal tears, perineal scarring	1
Anal gapping, rectal tears, proctoepisiotomy	1
TOTAL	104 (34%)

Normal-appearing anal and perianal regions were noted in 150 of 175 children (86%) who denied anal assault and in 11 of 70 (16%) who described anal assault. In comparison, anal and perianal abnormalities were observed in 57 of the 70 children (81%) who gave a clear history of anal assault but in only 23 of 175 (13%) who denied such abuse.

The anal and genital abnormalities among the children in this study group were correlated. Of the 310 patients, 125 children were found to have normal-appearing genitalia. Seventy-one patients had category 2 findings. Abnormalities suggestive of abuse were found in 114 (38%) patients. When the various genital abnormalities were compared with the presence or absence of perianal findings, children who had anal abnormalities were more likely to have normal genital examination (Table II). However, inclusion of genital findings increased the sensitivity of the medical evaluation. A combination of anal and genital abnormalities was seen in 53 (17%) patients, and either genital or anal abnormalities were found in an additional 182 (59%) patients. Only 75 (24%) patients had no abnormality of the genital or perianal regions. Even when only genital abnormalities highly suggestive of abuse were included (category 3), both anal and genital abnormalities were seen in 28 (9%) patients and either genital or anal abnormalities were found in an additional 159 (51%) patients.

Table II. Correlation between perianal and anal findings and genital abnormalities

	No. of patients		
Genital abnormalities	*Category 1*	*Category 2*	*Category 3*
Anal abnormalities present ($n = 104$)	51	22	27
Anal abnormalities absent ($n = 206$)	74	47	85

$\chi^2 = 6.314$, $p = 0.043$.

Comment

Anal abuse is a common form of sexual assault against children, particularly boys.[4,6] Although the genital abnormalities suggestive of sexual abuse have been described, there is no consensus regarding which perianal or anal abnormalities are the result of sexual abuse and which have other causes (e.g., constipation with passage of large, hard stools). Such determination may not be easy because the anal sphincter and anal canal allow some room for dilatation. A tear of the anal mucosa or sphincter rarely occurs after a digital assault. Penetration by a larger object may result in some degree of injury and may vary from a mere swelling of the anal verge to gross tearing of the sphincter. In the period immediately after penetration, sphincter laxity, swelling, and small mucosal tears of the anal verge may be observed. The swelling subsides and the mucosal tears heal within days; occasionally skin tags form. The anal sphincter regains function if it was not severed. Repeated acts of anal penetration over a prolonged period cause the anal sphincter to become loose, forming an enlarged opening.[9] The diagnosis of venereal disease affecting the anal canal is often delayed or even missed. When a child is infected with *Neisseria gonorrhoeae*, genital infection is associated with vaginal discharge and often the child is brought for medical care. Anal infection is often asymptomatic. Other disorders may cause perianal abnormalities similar to the ones observed in this series. Perianal abnormalities are often observed in children with Crohn's disease or Hirschsprung's disease. The anal canal gapes when the buttocks are gently drawn apart in children with significant constipation. This is a normal anorectal reflex initiated by the distended rectum. Usually stool may be seen in the anal canal. Minor small fissures may be seen after defecation for 2 to 3 weeks. Reddening of the perianal area may be found in children with fecal soiling.[7] Unfortunately, children who were abused often suffer from functional constipation and a damaged anal sphincter often causes fecal soiling.

Although many patients in this study group had normal-appearing perianal regions, the absence of physical findings is easily explained. Many victims of

anal assault do not sustain significant physical injuries because the anal sphincter and anal canal are capable of dilatation. Penetration, even by an adult penis, may occur without significant injury. The pain that follows anal assault may cause spasm of the anal sphincter and result in functional constipation, thus providing an explanation of the child's complaints of pain and rectal bleeding. Most children do not immediately disclose incidents of sexual abuse. Many victims do not have an examination for weeks, months, or even years after the abuse occurred. By then the injuries often have healed completely and the physical examination reveals few, if any, abnormalities.

Although we were able to detect a large number of children with anal and perianal abnormalities, it is difficult to conclude from this study which of these findings are diagnostic of anal abuse. The operating procedures of the clinic identify the patients as probable victims of sexual abuse at the time of registration; this may possibly cause bias by the examiner. More controlled studies are required to identify the specific findings indicative of anal assault. The association of other abnormalities (e.g., signs of neglect, genital injuries, etc.) should raise suspicion by the examiner that the patient is a victim of abuse. However, abnormal findings should not be interpreted in isolation. The findings of the medical examination must be correlated with other methods of validation such as a history from the child. To conclude from the findings of the medical examination alone that a child is a victim of abuse may cause enormous harm to the child and the family.[10]

As expected, children who were able to describe anal assault in detail were more likely to have perianal abnormalities. Memory of anal assault may suggest that the child experienced a more intense pain and thereby was more likely to have been injured. Fifty-nine of the 70 children (84%) who described anal assault had abnormalities on physical examination. In contrast, the examination was reported as normal in most instances when the child denied that anal assault had occurred. Observation of other abnormalities, particularly genital tract injuries, increases the sensitivity of the medical evaluation of child victims of abuse.

In this study group children who had normal results of the genital examination were more likely to have anal abnormalities. It is tempting to speculate that children who were primarily victims of anal assault were less likely to suffer a genital assault and thereby had a normal genital examination. I believe that this erroneous conclusion is caused by the inclusion of a significant number of male victims in this series. Only one male patient had genital abnormalities. All the remaining male patients had normal genital examinations, but a significant number of these had anal abnormalities, accounting for the erroneous impression.

"The etiology of most perianal fissures, irritation, and skin tags is often not evident, but may be trauma secondary to overzealous cleaning, constipation with passage of large hard stools, scratching induced by irritation from *Enterobius vermicularis* or eczema, or other perianal conditions."[11] Although the possibility of sexual abuse is not mentioned in this well-accepted textbook, child sexual abuse should be considered a potential cause of perianal injury. With the increasing number of children who are reported as victims, physicians who treat young patients must become proficient in the evaluation of sexual abuse. When abnormalities suggestive of perianal injury are detected, the physician should gently inquire about the possibility of sexual abuse. If such history can be obtained, further investigation is required. Some states have laws that require that all incidents of child sexual abuse be reported to a designated agency,[2] and many medical centers have developed multidisciplinary units for the evaluation of child victims of abuse.[12] Physicians may choose to refer patients whom they think have been sexually abused to these multidisciplinary units for further evaluation.

In summary, this study has documented that children who complained of anal assault are more likely to have some abnormality of the perianal region. Although these abnormalities are not always the result of sexual abuse, I suggest that when perianal abnormalities are detected, further evaluation may be required to protect a potential child-victim from further abuse. Such abnormalities could be considered as corroborating findings to a child's complaint of sexual assault.

Phosphorus 31 nuclear magnetic resonance examination of female reproductive tissues

Elizabeth A. Noyszewski, MSc, Jyothi Raman, MSc, Suzanne R. Trupin, MD, Barbara L. McFarlin, CNM, MS, and M. Joan Dawson, PhD

Urbana, Illinois

Nuclear magnetic resonance spectroscopy is a powerful method of investigating the relationship between metabolism and function in living tissues. We present evidence that the phosphorus 31 spectra of myometrium and placenta are functions of physiologic state and gestational age. Specific spectroscopic abnormalities are observed in association with disorders of pregnancy and gynecologic diseases. Our results suggest that noninvasive nuclear magnetic resonance spectroscopy examinations may sometimes be a useful addition to magnetic resonance imaging examinations, and that nuclear magnetic resonance spectroscopy of biopsy specimens could become a cost-effective method of evaluating certain biochemical abnormalities. (AM J OBSTET GYNECOL 1989;161:282-8.)

Key words: Magnetic resonance, ^{31}P nuclear magnetic resonance, metabolism, pregnancy disorders, gynecologic diseases

Nuclear magnetic resonance spectroscopy is a powerful method of investigating the relationship between metabolism and function in living tissues and is increasingly being used in studies of the cause of diseases. A related technique, magnetic resonance imaging, has an undisputed role in clinical diagnosis and is increasingly used in diagnosis of diseases of reproductive tissues.[1]

Nuclear magnetic resonance spectroscopy detects biochemical changes that cannot be assessed by other currently available diagnostic procedures. The phosphorus 31 nucleus emits strong signals from a small number of important compounds in living systems and yields estimates of intracellular pH and free intracellular magnesium (magnesium ion) concentration. The energetic status of an organ can be assessed and the concentrations of phosphorus compounds important to membrane synthesis, modulation, and degradation can be determined.

We present evidence that the ^{31}P nuclear magnetic resonance spectra of myometrium and placenta are a function of physiologic state and gestational age. Specific spectroscopic abnormalities are observed in association with disorders of pregnancy and gynecologic diseases. In some instances, these results support current hypotheses concerning the molecular abnormalities responsible for disease and suggest interesting new avenues to explore. Noninvasive nuclear magnetic resonance spectroscopy studies of female reproductive tissues are feasible; our results suggest that they may sometimes be a useful addition to magnetic resonance imaging examinations. However, such examinations are expensive and therefore limited to cases of clear need. Nuclear magnetic resonance spectroscopy could prove useful in quite a different way: as a cost-effective biochemical test on specimens now routinely assessed for histologic abnormalities.

Material and methods

Sample selection. Placenta from uncomplicated gestations were examined in each trimester. Data on placentas obtained from patients with complications of pregnancy are summarized in Table I and detailed in the Results section. The two hydatidiform moles were studied after evacuation at 7 and 10 weeks.

Normal myometria were examined from eight patients delivered of their infants by cesarean section at 34 to 39 weeks' gestation. Five of these uterine biopsies were performed at the time of elective repeat cesarean section and three were done after unaugmented labors. Myometria were examined from a single diabetic woman and a single hypertensive patient; placental samples were also available from these patients.

Tubal specimens were obtained at the time of postpartum ligation or at the time of hysterectomy. Samples of both normal and cystic ovarian tissues were also obtained.

Fourteen myometrial specimens were examined after hysterectomy in multiparous patients aged 30 to 87

Table I. Comparison of diseased and normal tissue

Tissue	*Disease*	*Alteration*	*p Value*
Myometrium	Hypertension	↑ PN (1.63)	<0.001
Pregnant	(n = 1)		
Nonpregnant	Adenocarcinoma	↑ PME (1.59)	<0.001
	(n = 2)	↑ Pi (1.92)	<0.001
Placenta	Growth retardation		
Third trimester	(n = 4)	↑ GPC (2.02)	<0.001
	Class A diabetes	↓ H^+ (0.16)	<0.003

First trimester	Hydatidiform mole	↑ PME (2.1)	<0.001
	(n = 3)	↓ H^+ (0.24)	<0.001

Number of samples in each category of diseased tissue is given in parentheses. Number of normal samples of myometrium were: pregnant, n = 7; nonpregnant, n = 12. Among normal placentas there were: third-trimester, n = 5; first-trimester, n = 6. Significance levels (p values) were estimated by an unpaired t test. *PN*, Pyridine nucleotide; *PME*, phosphomonoester; *Pi*, inorganic phosphate; *GPC*, glycerophosphorylcholine.

years. Indications for hysterectomy were as follows: two for uterine leiomyomas, one for adenomatous hyperplasia, two for endometrial adenocarcinoma, three for endometriosis, and six for other indications. The Institutional Review Board of the University of Illinois, Urbana-Champaign, approved this study.

Sample handling. After informed consent of the patient was obtained, samples of 100 to 500 mg of pregnant myometrium was trimmed from the edge of low transverse cervical incisions at the time of cesarean section. Samples were placed in oxygen-saturated modified de Jalon's solution (sodium, 170 mmol/L, chlorine, 177 mmol/L; piperazine-*bis*-2-ethane sulfonic acid (PIPES), 15 mmol/L; potassium, 6 mmol/L; glucose, 3 mmol/L, and calcium, 0.3 mmol/L) immediately after examination (within 0 to 2 minutes of delivery). Single lobules of placenta obtained from vaginal deliveries and cesarean section (third trimester) or from pregnancy terminations (first trimester) were also obtained and a small piece (3 to 4 gm) was placed in the ice-cold solution. Samples of uterine tube and ovary were also similarly handled. The pathologist was in the operating room to make his preliminary examination and to release tissues for study. The specimen jars were transported on ice (in a closed, thermally insulated box) to the nuclear magnetic resonance spectrometer. Tissues were superfused with oxygenated de Jalon's solution either at 4° C or 37° C within a 12 or 20 mm diameter nuclear magnetic resonance sample tube during nuclear magnetic resonance spectroscopy examination. Data acquisition was generally completed within 1 to 2 hours.

Nuclear magnetic resonance spectroscopy procedures. ^{31}P nuclear magnetic resonance spectra were obtained at 121.48 MHz on a GN300 wide-bore spectrometer (General Electric, Fremont, Calif.), pulse duration = 20 μsec, flip angle = 35 degrees, pulse interval = 1.5 sec. Resonance positions were measured relative to that of an internal standard in parts per million (i.e., 121.48 Hz = 1 ppm). When possible, the phosphocreatine resonance was used as the internal standard; for the placenta, which often contains no phosphocreatine, the position of the α-nucleotide phosphate peak was used as a reference because in all tissues studied this peak had the most constant chemical shift relative to phosphocreatine (in the uteri reported here, δ(phosphocreatine − α-nucleotide phosphate) = −7.55 ± 0.02, n = 15). Line broadening of 5 Hz was used to reduce noise in the spectra, but no other signal-enhancement procedures were applied. Peaks were assigned on the basis of their resonance positions and the known presence of particular metabolites in the tissue. In some cases unambiguous assignment awaits tissue extraction and further analysis.

The intracellular concentrations of hydrogen and magnesium ions were calculated from the general formula:

$$pX = pK + \log_{10} \frac{\delta - \delta_1}{\delta_2 - \delta}$$

where X = hydrogen or magnesium ions and δ is the observed chemical shift of a titratable species (inorganic phosphate in the pH calculation and β-nucleotide triphosphate in the calculation of free magnesium ions). For the pH calculation at 4° C, pK = 6.71, δ_1 = 3.19, and δ_2 = 5.49, and for magnesium ions, δ_1 = 15.86, δ_2 = 19.02, and pK = 4.11.

Quantitation. Provided that the interval between radiofrequency pulses is more than five times the apparent T_1 relaxation time for the phosphorus nuclei, the peak areas are directly proportional to the concentrations of metabolites present. To determine the effect of pulse interval, spectra were collected at intervals of 1.0, 1.5, 3, 5.5, 10.5, and 15.5 seconds. The sizes of the signals obtained at 1.5-second intervals (the pulse interval used routinely) were then corrected with the ap-

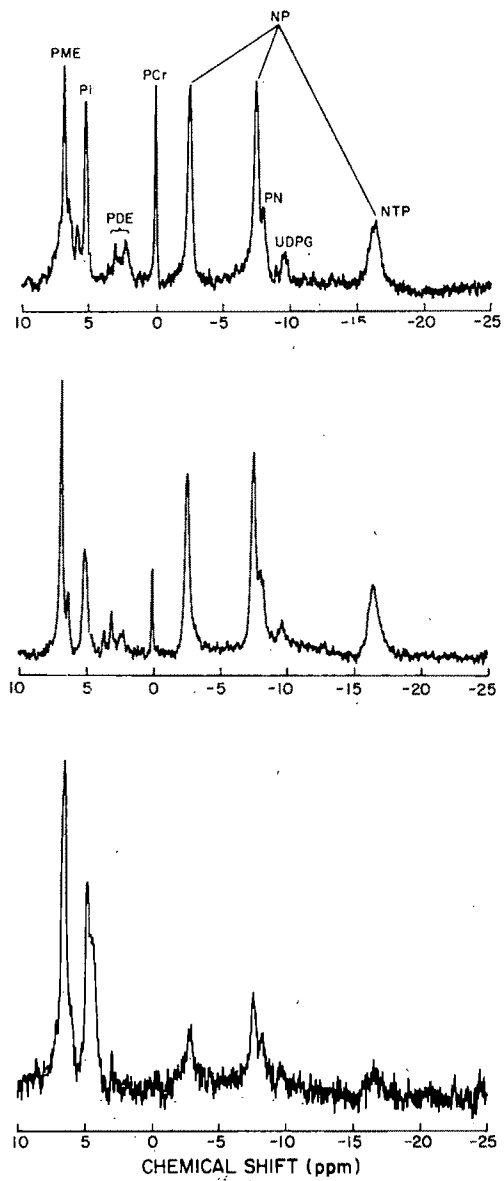

Fig. 1. ^{31}P nuclear magnetic resonance spectra from term pregnant *(top)* and nonpregnant *(middle)* normal myometrium and normal myometrium accompanying endometrial adenocarcinoma *(bottom)*. Isolated myometria (100 to 500 mg) were superfused with oxygenated de Jalon's solution at 4° C. The *y* axes have been adjusted so that, for any given peak, equal signal intensities in the three spectra represent equal concentrations of metabolites. *PME,* Phosphomonoester; *Pi,* inorganic phosphate; *PDE,* phosphodiester; *PCr,* phosphocreatine; *UDPG,* uridine diphosphoglucose; *PN,* pyridine nucleotide (nicotinamide adenine dinucleotide and nicotinamide adenine dinucleotide phosphate, both oxidized and reduced); *NTP,* nucleotide triphosphate (primarily adenosine triphosphate); *NP,* nucleotide phosphate (primarily adenosine triphosphate plus adenosine diphosphate).

propriate saturation correction factors, which were determined from the T_1 relaxation equation for steady-state conditions.[2] There was no significant difference between T_1 values obtained for pregnant and nonpregnant uterus. The total corrected signal intensity per wet weight of tissue also did not differ. Therefore ratios of signal intensity divided by total intensity are equivalent to concentration ratios.

The concentration of nucleotide triphosphate is estimated from the corrected integral of the β–nucleotide triphosphate peak, which contains no contribution from nucleotide diphosphates. The concentration of nucleotide diphosphate is estimated by subtracting the integral of the β–nucleotide triphosphate peak from that of the γ-nucleotide phosphate peak, which contains contributions from both nucleotide triphosphate and nucleotide diphosphate. The concentration of pyridine nucleotide (nicotinamide adenine dinucleotide and nicotinamide adenine dinucleotide phosphate, both oxidized and reduced forms) is estimated by subtraction of γ from the α–nucleotide phosphate peak, which contains contributions from all of the nucleotide and pyridine phosphates.

Data analysis and presentation. A tissue evaluation form was attached to the nuclear magnetic resonance spectroscopy records to facilitate correlation of nuclear magnetic resonance spectroscopy data with clinical evaluation; the nuclear magnetic resonance spectroscopy findings were attached to the patient's charts. A spread sheet has been developed to facilitate comparisons of the nuclear magnetic resonance data with the clinical and pathologic findings relevant to the diagnosis of the tissue sample. Data manipulation, graphical representation, and statistical analysis were done with the Asyst software package (Macmillan Software, New York). In comparisons of diseased with normal tissue, or studies of changes in the spectrum as a function of physiologic state of the tissue, data are reported as significantly different if they reach a p value >0.01.

The results and figures shown for concentrations of phosphorus metabolites and free magnesium ions are taken from studies of superfused tissues at 4° C, because this (rather than the more complicated perfusion techniques required to maintain tissues at 37° C) could become a routine procedure in a clinical setting. Under these experimental conditions the myometria, uterine tubes, and ovaries are stable for 12 to 24 hours, as judged by the ^{31}P nuclear magnetic resonance spectra, visual inspection, and tissue weight. Difficulty was experienced in maintaining third-trimester (but not first-trimester) placentas in a metabolically stable state; care was taken to complete the experiments within 1 to 2 hours after delivery. In some cases tissues were perfused or superfused at 37° C and identical results were obtained.

Results

Myometria. Fig. 1 shows typical ^{31}P nuclear magnetic resonance spectra from normal term pregnant (top panel) and nonpregnant (middle panel) myometrium,

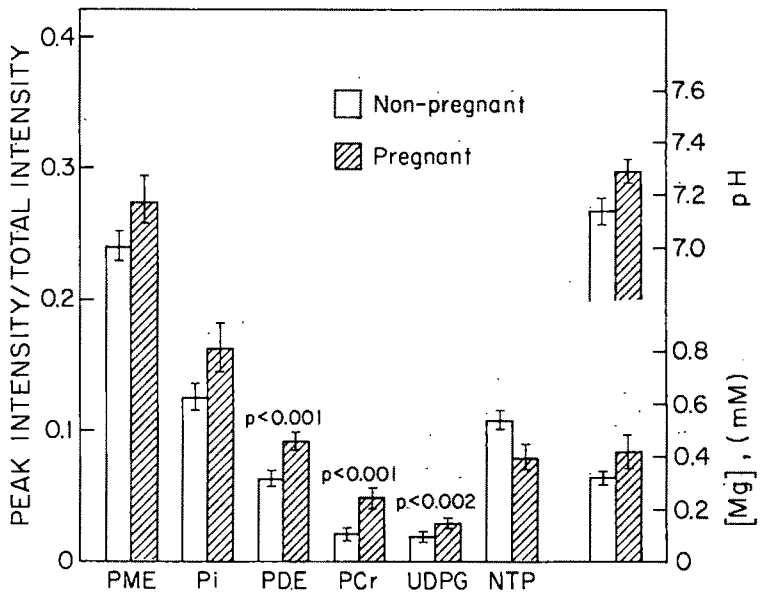

Fig. 2. Summed results on all normal pregnant (n = 7) and nonpregnant (n = 12) myometria, excluding grossly normal specimens from patients with adenocarcinoma. *Error bars* represent ±SEM; p values are for unpaired t test described in Methods. All peak intensities are corrected for saturation so that relative heights of bars are equivalent to relative concentrations. For abbreviations, see Fig. 1 legend.

and grossly normal myometrium from a patient with endometrial adenocarcinoma (bottom panel). The individual nucleotide phosphates resonate so close to each other that they are indistinguishable in the spectra. Adenine is the major (75%) nucleotide in the uterus; its contribution to the total nucleotide phosphate pool does not change with pregnancy.[3] The peak at 6.8 ppm in the phosphomonoester region of the spectrum is in the position of phosphoethanolamine, and the shoulder on the right of this peak is in the position of phosphocholine.[4] Two of the peaks in the phosphodiester region of the spectrum have been identified in mammalian reproductive tissues[4] as glycerophosphorylethanolamine (3.5 ppm) and glycerophosphorylcholine (3.1 ppm). Our spectra of myometria show two peaks, which to our knowledge have not previously been observed: one in the phosphomonoester region at 5.9 ppm and one in the phosphodiester region at 2.3 ppm.

Results of normal myometrium samples are summarized in Fig. 2. There is no significant difference between pregnant and nonpregnant myometrium in concentrations of phosphoethanolamine, inorganic phosphate, and nucleotide triphosphate, whereas phosphocreatine, phosphodiester, and uridine diphosphoglucose are significantly higher in term pregnant than nonpregnant myometrium. Although concentrations are too low for accurate individual quantitation, in pregnant myometrium the peak attributed to glycerophosphorylethanolamine is generally too low for detection and the increase in phosphodiester is largely caused by elevated intensity of the unassigned peak at 2.3 ppm. The unidentified peak at 5.9 ppm is consistently higher in term pregnant than nonpregnant uterus.

Nuclear magnetic resonance spectra of grossly normal myometrium from the two patients with endometrial adenocarcinoma (Fig. 1, bottom panel, and Table I) showed striking differences compared with other myometrial samples. The same spectral characteristics (high phosphoethanolamine and inorganic phosphate with an absence of phosphocreatine) have been observed in cultured human adenocarcinoma cells[5] and in a metastatic adenocarcinoma in the liver.[6] All of the macroscopically normal nonpregnant myometrium obtained from hysterectomies for other reasons, including cervical cancer, showed no ^{31}P spectral biochemical differences from one another. A nondegenerating leiomyoma showed a clearly different biochemical profile from the surrounding normal tissue, including a large acid shift in pH. The myometrial sample obtained from a single patient with hypertension showed significantly increased pyridine nucleotide, as documented in Table I.

Placentas. Fig. 3 shows normal ^{31}P nuclear magnetic resonance spectra of first- and third-trimester placentas (solid lines) and examples of abnormalities (dashed lines). Fig. 4 represents the results on normal first- and third-trimester placentas in graphic form. The relative peak intensities for phosphomonoester, pyridine nucleotide, and nucleotide triphosphate decrease significantly as normal pregnancy progresses, whereas the intensity of the inorganic phosphate peak is substantially increased over the same period.

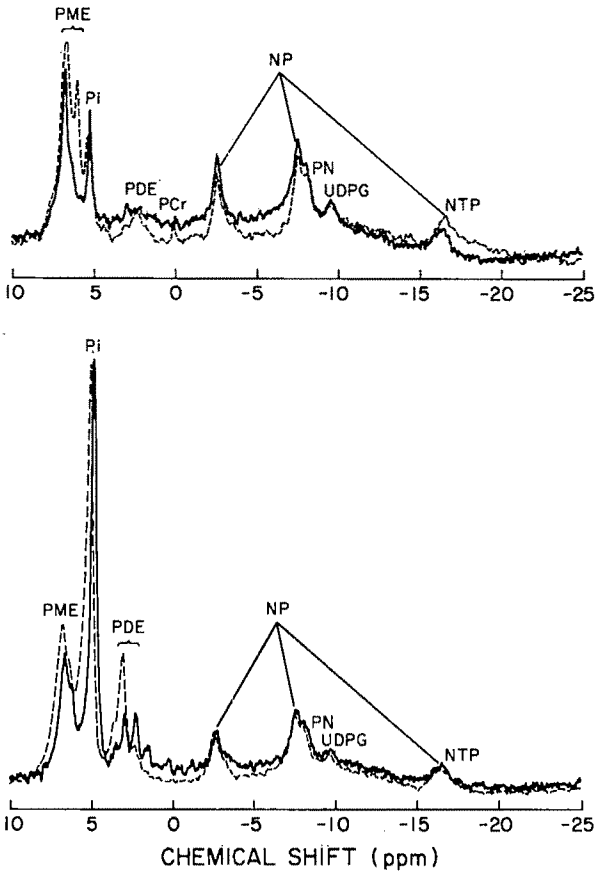

Fig. 3. ^{31}P spectra of normal and abnormal first-trimester (9 to 14 weeks, *top panel*) and third-trimester (35 to 41 weeks, *bottom panel*) placentas. *Solid lines* represent normal placentas and show normal biochemical changes with maturation. Superimposed *dashed lines* represent abnormalities of same gestational age: a 7-week hydatidiform mole and a growth-retarded placenta at 40 weeks. The *y* axes have been adjusted so that for any given peak equal signal intensities represent equal concentrations of metabolites. For abbreviations, see Fig. 1 legend.

The hydatidiform moles (Fig. 3, top, dashed line) show a higher than normal signal intensity in the phosphomonoester region, largely as a result of an increase in the unknown peak at 5.9 ppm, and a decrease in intensity of the inorganic phosphate peak. Placentas from patients with intrauterine fetal growth retardation (Fig. 3, bottom, dashed line) showed a marked increase in the glycerophosphorylcholine peak intensity, together with a significantly alkaline pH in comparison to normal placentas of the same gestational age.

The diabetic patients made up a distinctly abnormal group with a significant intracellular alkalinization that tended to increase with the severity of the disease. Each of the two drug abusers who were studied showed marked abnormalities in their placental ^{31}P spectra; the two spectra did not resemble one another, but neither did their patterns of drug abuse.

Uterine tube and ovary. Spectra from uterine tubes (Fig. 5, top) and ovaries (Fig. 5, bottom) have also been obtained. As might be expected, the spectra from uterine tubes are very similar to those of myometria. The average phosphocreatine/adenosine triphosphate ratio in the three uterine tubes studied was not significantly different from that of nonpregnant myometrium; magnesium binding to adenosine triphosphate was also similar. In the ovarian samples obtained, the phosphocreatine peak is clearly visible and the pH was similar to that of the other reproductive tissues studied. The ovarian cyst showed a higher inorganic phosphate and phosphoethanolamine and a much higher uridine diphosphoglucose than the normal tissue.

Comment

This ^{31}P nuclear magnetic resonance spectroscopy survey of isolated human reproductive tissue has yielded previously unavailable biochemical information and leads to testable hypotheses concerning the relationship between metabolism and function in normal and diseased conditions. Although the number of samples analyzed to date is small, highly significant differences were observed between normal and diseased tissues, suggesting the possibility that accurate diagnostic assessments of the severity of disease could be developed on the basis of these or similar techniques.[7] Continued studies of the biochemical abnormalities we have found could lead to a better understanding of the molecular bases of common reproductive disorders.

When comparison is possible, the results of this study are in good agreement with the results of similar studies of rat tissue (pregnant or nonpregnant uterus,[8] ovary,[4] term placenta[9]), in which dissection was done in the laboratory under controlled conditions and nuclear magnetic resonance analysis was immediately begun. A similar result was also obtained in a single noninvasive study of intact nonpregnant rabbit uterus.[10] For this reason, we believe that our results are reasonable estimates of in vivo tissue metabolite concentrations and how these change with physiologic state.

Tissue specific characteristics and hormonal control. For all of the normal samples, the tissue of origin and its physiologic status can be deduced by inspection of the ^{31}P spectrum. The differences among tissue types relate to the concentrations of phosphorus metabolites involved in generation, storage, and use of metabolic energy (phosphocreatine, nucleotide triphosphate, nucleotide phosphate, pyridine nucleotide, inorganic phosphate), to intracellular pH and free intracellular magnesium concentration, and to the concentrations of phosphomonoesters and phosphodiesters, which are intermediates in membrane synthesis, degradation, and modulation.[11]

The changes observed as a result of pregnancy in

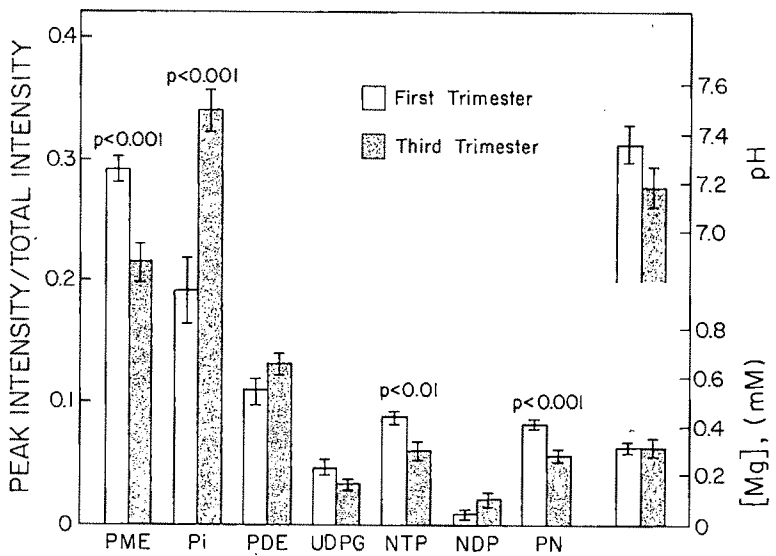

Fig. 4. Summed results of normal first-trimester (n = 6) and third-trimester (n = 5) placentas. Data processing and statistical methods are the same as in Fig. 2, with the exception that no correction for saturation was made. For abbreviations, see Fig. 1 legend.

both rat[8] and human myometrium[7] reflect an increase in energy stores and tend to prepare the uterus for the effort of labor. For example, uridine diphosphoglucose is an intermediate in glycogen synthesis, and phosphocreatine is a buffer for the supply of adenosine triphosphate. Animal studies suggest that phosphocreatine in the myometrium is under hormonal control.[8, 12] There have been suggestions that myometrial intracellular magnesium ions are under hormonal control[12] and we have reported preliminary evidence that free intracellular concentrations of magnesium ions may vary in myometrium and placenta as a result of physiologic status and disease.[7] The results obtained in our study are consistent with these previous observations; both hypertensive and diabetic patients show changes in placental free magnesium ions at the 0.05 level of significance. We have previously suggested that the pronounced increase in inorganic phosphate concentration as a result of placental maturation could be related to phosphorus transport to the fetus and that the decreased phosphomonoester with gestational age could be related to decreased cell turnover.[7]

Proliferative diseases. Currently there is great emphasis in the assessment of the roles of ^{31}P nuclear magnetic resonance spectroscopy in the diagnosis and prognosis of cancer. Our results and those of others who studied breast tumors[13] suggest that the reproductive tract may be particularly ammenable to nuclear magnetic resonance spectroscopy examination. Benign breast tumors have substantially lower phosphoethanolamine content than breast cancers.[14] Our results suggest that grossly normal myometrium from patients with adenocarcinoma (in one case, with no myometrial

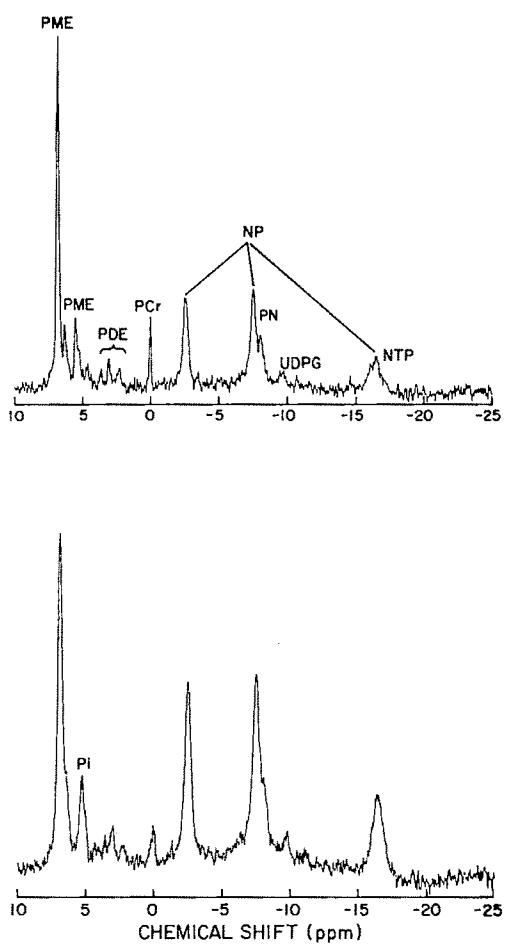

Fig. 5. ^{31}P nuclear magnetic resonance spectra of normal human uterine tube *(above)* and ovary *(below)* superfused at 4° C with oxygenated de Jalon's solution. For abbreviations, see Fig. 1 legend.

invasion) shows characteristics typical of the disease and suggest that ^{31}P nuclear magnetic resonance spectroscopy might provide information of prognostic significance. Conversely, the myometria studied from patients with cervical cancers showed no spectral abnormalities, consistent with a disease that would not normally first spread to the myometrium.

Disorders of pregnancy. The concentrations of high-energy phosphates generally are not altered in the diseased tissues we study, but there are other, more specific spectral changes. For example, the intrauterine growth retardation is associated with an increase in the placental peak attributed to glycerophosphorylcholine; this is consistent with an abnormality in placental membrane composition. A decrease in the intensity of this peak is observed in the skeletal muscle dystrophies,[15] which are known to be associated with abnormal membrane composition. Patients with diabetes show an alkaline placental intracellular pH, consistent with the finding that insulin alters intracellular pH in other tissues.[16]

The future. In an initial study clearly it is possible only to explore the usefulness of nuclear magnetic resonance spectroscopy for diagnosis and for elucidating the cause of disease. The results have been promising and one can imagine routine clinical determinations of placental biochemistry becoming an integral part of patient management. Nuclear magnetic resonance spectroscopy examinations in conjunction with magnetic resonance imaging, although not yet commonplace, yield useful information in selected cases. Our results suggest that endometrial adenocarcinoma might be one of those cases.

Finally, it is now possible to evaluate tissue biopsy samples of 10 to 50 mg blotted weight by ^{31}P nuclear magnetic resonance spectroscopy. We are doing so in preliminary studies of endometrial samples. Therefore nuclear magnetic resonance spectroscopy evaluation of the biochemistry of biopsy specimens on which histologic examinations are now obtained is feasible. Studies of small tissue samples, in contrast to noninvasive nuclear magnetic resonance spectroscopy examinations, involve relatively small capital and running costs and could therefore become routine diagnostic or screening procedures if their utility were to be adequately demonstrated.

A new surgical technique to treat refractory labial fusion in the elderly

N. Johnson, MRCOG, FRCS, R. J. Lilford, MRCOG, MRCP, PhD, and D. Sharpe, FRCS, OBE

Leeds and Bradford, England

An elderly woman with refractory labial fusion was treated by labial separation. The subsequent raw area was covered by a rotational skin flap from the thigh. The flap was deroofed of epithelium proximally and tunnelled subcutaneously. The distal portion emerged to cover the raw clitoral area and this successfully prevented contraction and scarring. (Am J Obstet Gynecol 1989;161:289-90.)

Key words: Labial fusion, dyspareunia, clitoris, vulvovaginitis.

A menopausal woman with dyspareunia was first seen with labia minora that could not be separated. Previous treatment attempts failed and the labia minora reunited. A technique suitable for such cases in elderly patients is presented.

Case report

A 53-year-old menopausal female was first seen in good health with a 3-year history of superficial dyspareunia. This was a result of anterior fusion of her labia minora. Three years previously a Fenton procedure combined with surgical separation of the adherent labia was attempted and various hormonal creams were applied to the vulva. These attempts failed and the labia reunited in the midline and obscured the clitoris. In the past, she was delivered of three children vaginally.

Examination of the vulva revealed that both labia minora were united to each other in the midline by a dense fibrous union that could not be separated. The clitoris was completely buried and could not be palpated. The rest of the vulva was atrophic but there were no dystrophic changes.

Under general anesthetic and in the lithotomy position the labia minora were separated along their natural line of cleavage by blunt and sharp dissection. Left alone, the raw edges of the labia came together and it was apparent that even if they were held apart by lateral anchoring sutures the raw area would have strictured and stenosed. It was decided to cover this area by a full-thickness skin flap to prevent contraction and scarring. This was fashioned from the medial aspect of the left thigh (2 inches × 1 inch; Fig. 1). The proximal half of this flap was deroofed of its epithelium by sharp dissection. The flap was rotated around an axis of 90° and was tunnelled subcutaneously until it emerged over the epithelial defect caused by the separation of labia minora. The deroofed epithelium lay under the tunnel and the full-thickness distal portion of the flap covered the raw area above the clitoris. It was secured into place with interrupted monofilament sutures (Fig. 2). The donor site was closed and the patient made an uneventful recovery.

Fig. 1. Labia minora were separated and full-thickness skin flap was fashioned from medial aspect of left thigh.

On the fifth postoperative day the wound was reexamined, and the sutures that secured the healthy flap were removed. By the third postoperative week the flap and donor site had completely healed and the introitus comfortably admitted two fingers. The patient has resumed vaginal intercourse and experiences clitoral stimulation.

Comment

Labial adhesions are generally considered to supervene inflammation in the prepubertal and hypoestrogenized female. However, older women are not immune from the condition[1] and they may have dyspareunia. Most cases can be treated by the application of topical, bland, or estrogen creams and gentle manip-

From the Department of Obstetrics and Gynaecology, St. James's University Hospital, and the Department of Plastic Surgery, Bradford Royal Infirmary.

Fig. 2. Proximally, flap is buried subcutaneously and emerges to cover raw area over clitoris. Full-thickness distal portion of flap is secured with interrupted sutures.

ulation. In extreme cases the labia may be separated and held apart with anchoring sutures. However, if the labia are firmly adherent and their separation leaves a large raw area, contraction of the overlying epithelium will occur and cause further stenosis of the introitus, which is likely to be refractory to further treatment. Stricture and scarring can only be prevented by covering the area with a full-thickness skin flap that contains its own blood supply. The only alternative would involve several releasing incisions closed with Z-plasty techniques,[2] but this would still leave the patient with a scarred vulva and wounds over the clitoral area.

The only significant potential complication of the technique we described is flap ischemia. The flap's viability is particularly at risk because it was deepithelialized proximally and because it possesses a random blood supply without a major vascular pedicle. Poor blood flow to the flap can result in wound infection, necrosis, and even sloughing. However, if the flap had failed, the patient would have been left with a homozygous dressing of natural skin that could have been easily regrafted.

This new technique is suitable in elderly patients with cases of labial adhesion that are refractory to all other treatment modalities.

Bound volumes available to subscribers

Bound volumes of the American Journal of Obstetrics and Gynecology are available to subscribers (only) for the 1989 issues from the Publisher, at a cost of $56.00 ($79.00 international) for Vol. 160 (January-June) and Vol. 161 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the Journal name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C.V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular Journal subscription.

Predictive values, relative risks, and overall benefits of high and low maternal serum α-fetoprotein screening in singleton pregnancies: New epidemiologic data

Aubrey Milunsky, MB, BCh, DSc,[a] Susan S. Jick, MPH,[b] Carol L. Bruell, MS,[a] Dean S. MacLaughlin, PhD,[b] Yean-Kai Tsung, PhD,[a] Hershel Jick, MD,[b] Kenneth J. Rothman, DrPH,[c] and Walter Willett, MD[d]

Boston, Massachusetts

In a prospective study of maternal serum α-fetoprotein screening for both high and low values, we assessed the overall predictive value, sensitivity, specificity and relative risks for congenital defects and complications of pregnancy. Among 13,486 women with singleton pregnancies interviewed at the time of screening (15 to 20 weeks of gestation), 3.9% had high and 3.4% had low values. A high maternal serum α-fetoprotein value was associated with the following adverse outcomes: neural tube defects (relative risk = 224), other major congenital defects (relative risk = 4.7), fetal deaths (relative risk = 8.1), neonatal death (relative risk = 4.7), low birth weight (relative risk = 4.0), newborn complications (relative risk = 3.6), oligohydramnios (relative risk = 3.4), abruptio placentae (relative risk = 3.0) and preeclamptic toxemia (relative risk = 2.3). A low maternal serum α-fetoprotein value was associated with chromosomal defects (relative risk = 11.6) for fetal death (relative risk = 3.3). Either *high or low* maternal serum α-fetoprotein values were associated with 34.2% of all major congenital defects, 19.1% of all stillbirths and fetal-neonatal deaths, 11.0% of major pregnancy complications, and 15.9% of serious newborn complications. Maternal serum α-fetoprotein screening provides an important adjunctive tool for the identification of high-risk pregnancy and adverse neonatal outcome. (AM J OBSTET GYNECOL 1989;161: 291-7.)

Key words: α-Fetoprotein, neural tube defects, Down's syndrome, obstetric complications

Screening for elevated values of maternal serum α-fetoprotein is currently the standard of expected obstetric care in the United States and must be offered in California by law. More than a decade of experience has supported the introduction of routine screening into obstetric practice.[1] Evaluation of low maternal serum α-fetoprotein values for Down syndrome screening currently remains a research area, notwithstanding accumulating reports of benefits.[2-4] Surprisingly few epidemiologic studies have been conducted to evaluate the predictive values and relative risks associated with either elevated or low maternal serum α-fetoprotein values in the same cohort. In this prospective study we assess the sensitivity, specificity, overall predictive values, and relative risks of neural tube and other congenital defects (NTDs), chromosomal abnormalities, and pregnancy complications associated with high and low values in a maternal serum α-fetoprotein screening program.

Material and methods

All pregnant women receiving routine prenatal care in the practices of more than 90 participating obstetricians were offered maternal serum α-fetoprotein screening. Only occasional (estimated at <2%) patients declined screening. A serum sample was received by our Center for Human Genetics for 17,405 patients. As part of a study of antecedents to NTDs and other congenital defects, each woman was telephoned by one of our trained nurses for an interview. A total of 16,487 women whose serum samples were received consented to the interview; only 918 (5.3%) declined.

Interviews were conducted between Oct. 1984 and June 1986, and focused specifically on family, medical, and obstetric history with special emphasis on diet, medications, and illness during the first trimester of pregnancy. Questions also covered the environmental

Table I. Selected outcomes after maternal serum α-fetoprotein screening in 13,486 pregnancies

and occupational exposures within the year before conception. The vast majority of the interviews occurred before the maternal serum α-fetoprotein screening results were known to either the patient or the interviewer; 94% of patients in this study were between 15 and 20 weeks' gestation.

Pregnancy outcome was ascertained from a brief questionnaire mailed to the delivering physicians or eventually to the mothers themselves when necessary. Basic information concerning delivery, birth, pregnancy complications, and newborn health was the focus of this questionnaire.

This article reflects the outcome data for 13,486 (82%) of the interviewed women. Approximately 1500 had not yet been delivered at this time. (Subsequently, 159 women with multiple pregnancies were excluded.) Physicians provided 84% of the outcome data; the remaining 16% of the outcome questionnaires were completed by mothers. To date 10% have been lost to follow-up.

Low birth weight was defined as <5.5 pounds. Well-established criteria were used to define major and minor birth defects.[5] Newborn complications included any "special care" of the infant within the first few days of life such as surgery or treatment of jaundice, infection, respiratory difficulty, or complications of prematurity. Pregnancy complications included intrauterine growth retardation, abruptio placentae, placenta previa, precipitate labor, shoulder dystocia, nuchal cord, premature labor, postmaturity (>42 weeks' gestation), bleeding during pregnancy, or fetal loss.

Maternal serum α-fetoprotein assays were done by radioimmunoassay (Clinical Assays, Cambridge, Mass.) as previously reported.[6] Ultrasonographic studies were routinely requested for determination of an accurate gestational age for all mothers whose maternal serum α-fetoprotein values were ≥2.0 multiples of the median or ≤0.4 multiple of the median in the initial phase of the study and later when the odds for Down syndrome were ≥1:270 (see explanation below). Level II ultrasonography was recommended after confirmation of gestational age for maternal serum α-fetoprotein values between 2.0 and 2.4 multiples of the median. Amniocenteses were recommended in all pregnancies after confirmation of gestational age when maternal serum α-fetoprotein values were ≥2.5 multiples of the median or early in the study when the maternal serum α-fetoprotein value was ≤0.4 multiple of the median and subsequently if the odds for Down syndrome were ≥1:270. Later, consistent with practice in other major United States maternal serum α-fetoprotein screening centers, the lower-limit cutoff was changed to reflect

odds for Down syndrome. These odds were chosen because they were equivalent to known midtrimester risks for women aged 35 years who were routinely informed of such risks and the option of amniocentesis. The actual maternal serum α-fetoprotein level at these odds were in fact very close to the ≤0.4 multiple of the median used initially. Pregnancies that spontaneously aborted (categorized as fetal death) or were terminated for a diagnosed fetal defect were included among known outcomes.

Relative risks of specific outcomes and 95% confidence intervals were calculated for women with high or low maternal serum α-fetoprotein values, and women with normal values were used for comparison.[7] Sensitivity, specificity, and predictive values were computed for high and low maternal serum α-fetoprotein values.

Results

The age range of the 13,486 women in this study extended from 14 to 43; 90% of the women were 20 to 34 years old. Demographic information was available for 97.2% of the subjects. Ninety-four percent of the subjects were white, 1% each were black, Oriental, or of other races, and 2.8% were unknown. Eighty-two percent lived in the Boston area, 11% lived elsewhere in Massachusetts, 3.6% elsewhere in New England, 1% in states distant to New England, and in 2.8% residence information was not available.

Pregnancy outcomes after second-trimester maternal serum α-fetoprotein screening in 13,486 women are summarized in Table I. Of these, 12,495 women (92.7%) had a normal maternal serum α-fetoprotein value, 530 (3.9%) had a high value, and 461 (3.4%) had a low level. Women with a high level were at increased risk for pregnancies resulting in NTDs (relative risk = 224), other major congenital defects (relative risk = 4.7), fetal deaths (relative risk = 8.1), neonatal death (relative risk = 4.7), and newborn complications (relative risk = 3.6). Increased relative risks were also noted for major pregnancy complications including oligohydramnios (relative risk = 3.4), abruptio placentae (relative risk = 3.0), and preeclamptic toxemia (relative risk = 2.3).

Women with low maternal serum α-fetoprotein values were almost 12 times more likely to have offspring with a chromosome defect and were more than three times more likely to suffer a fetal death when compared with women with normal levels.

We next calculated the sensitivities, specificities, and predictive values of the maternal serum α-fetoprotein screen with respect to those outcomes for which the high or low maternal serum α-fetoprotein value indicates an increased risk for an abnormal outcome (see Table II). The sensitivity of the maternal serum α-fetoprotein test is quite low except in the case of spina bifida (sensitivity = 90.9%) and anencephaly (sensitivity = 100%), indicating that for most outcomes the test does not detect a majority of the cases. The positive predictive values, which indicate what percentage of a positive test will result in an abnormal outcome, are also low. This is a reflection of both the low prevalence of the outcomes and the small number of abnormal outcomes that follow a positive test. However, the specificity values are uniformly quite high; all are approximately 96; this indicates that most women who had a

§Subtotals, nonhierarchical.

normal pregnancy outcome also had a normal maternal serum α-fetoprotein level. Similarly, the negative predictive values, which indicate what percentage of people with a normal test result will have a normal outcome, are uniformly high. This is a reflection of the low prevalence of the various outcomes, and the large proportion of women with normal test levels who had normal pregnancy outcomes.

From Table II it can be inferred that all fetuses with anencephaly (nine cases) were detected through maternal serum α-fetoprotein screening. For spina bifida, 10 of 11 cases were detected; this yielded the high sensitivity rate of 90.9%. One of two fetuses with encephalocele had an associated elevated maternal serum α-fetoprotein level.

Since multiple adverse outcomes commonly occurred in the same pregnancy, we also constructed a hierarchical table, with each case being counted only once, for the outcome judged to be the most serious (see Table III). Selected pregnancy outcomes are tabulated for normal, high, and low maternal serum α-fetoprotein values. Calculations from the figures in Table III showed that the frequency of all major congenital defects combined was 0.9%. All fetal or neonatal losses combined also occurred in 0.9% of screened women. These major pregnancy complications combined occurred in 5.1%, whereas a further 2.9% had other miscellaneous pregnancy complications. Newborn complications occurred in 1.2% of cases.

Calculations from the data in Table III indicate that 34.2% of all major congenital defects combined were associated with either a high or low maternal serum α-fetoprotein value. Similarly, 19.1% of all fetal-neonatal losses had high or low maternal serum α-fetoprotein values; 11.0% of major pregnancy complications and 15.9% of newborn complications were associated with abnormal levels. High or low maternal serum α-fetoprotein values were associated with a further 8.3% of miscellaneous pregnancy complications. The one fetus listed under chromosome defects and high maternal serum α-fetoprotein values (Table II) had triploidy and spina bifida and therefore does not appear under chromosome defects in the hierarchical Table III.

Of the 530 women with elevated maternal serum α-fetoprotein values, 32 (6.0%) had a fetus with some type of major congenital defect, compared with 81 (0.6%) among women with a normal value. Fetal or neonatal loss occurred in 16 (3.0%) of women with high values, whereas a major pregnancy complication was observed in 53 (10.0%). Among women with normal

maternal serum α-fetoprotein values, these losses occurred in 102 (0.8%) and 615 (4.9%) women, respectively. Newborn complications were noted in 18 (3.4%) among the group with high values and in 132 (1.1%) among those with normal values.

Among the 461 patients with low maternal serum α-fetoprotein values, 6 (1.3%) had chromosome defects (two with trisomy 21, two with trisomy 18, an unbalanced 14/21 translocation Down syndrome, and a mosaic XO/XX/XXX), compared with 14 (0.1%) among those with normal maternal serum α-fetoprotein values. None of these patients were of advanced maternal age. Among the 461 patients, 5 (1.1%) experienced a fetal death and 8 (1.7%) lost their fetuses or newborns, compared with 38 (0.3%) and 102 (0.8%), respectively, among those with normal maternal serum α-fetoprotein values.

The probabilities of specific pregnancy outcomes related to previous normal, high, and low maternal serum α-fetoprotein values are shown in Table IV. Of special note for outcomes associated with high values is the 1:28 probability for NTDs, 1:17 for all major congenital defects combined, 1:10 for the major pregnancy complications, and 1:29 for clinically important newborn complications. For the group of outcomes associated with low maternal serum α-fetoprotein values, of special importance is the 1:77 probability for chromosome defects, 1:46 for all major congenital defects combined, and 1:20 for the specifically named major pregnancy complications.

The other major congenital defects associated with either a high or low maternal serum α-fetoprotein value are included in the footnote in Table III. The five neonatal deaths included four with prematurity complications and one with multiple congenital anomalies.

Table IV. Probabilities of selected pregnancy outcomes for normal, high, and low maternal serum α-fetoprotein values

Pregnancy outcome	*Probabilities for maternal serum α-fetoprotein*		
	Normal	*High*	*Low*
NTDs	1:6247	1:28	0
Chromosome defects	1:892	0	1:77
Other major congenital defect	1:192	1:41	1:115
All major congenital defects combined	1:154	1:17	1:46
Stillbirth, fetal or neonatal death	1:122	1:33	1:58
Premature rupture of membranes	1:40	1:21	1:46
Preeclamptic toxemia	1:69	1:29	1:51
Oligohydramnios, polyhydramnios, abruptio placentae, toxemia, and premature rupture of membranes	1:20	1:10	1:20
Newborn complications	1:95	1:29	1:66

The outcome categories are mutually exclusive, each case was counted only once on the basis of the hierarchy in Table III.

Comment

This prospective study of singleton pregnancies documents the increased relative risks associated with elevated or low maternal serum α-fetoprotein values, extends the number and type of pregnancy complications associated with abnormal values, and demonstrates the overall benefits of screening for both high and low maternal serum α-fetoprotein values. An increased maternal serum α-fetoprotein level in this study yields a striking relative risk of 224 for NTDs and a relative risk of 4.7 for other major congenital defects.

Other authors have previously noted increased relative risks in the range of 4 to 5 for low birth weight among pregnant women with high maternal serum α-fetoprotein levels,[8, 9] as we report here. Relative risks of perinatal death varying from 6 to 11[8, 10, 11] are comparable to our findings of 8.1 for fetal death and 4.7 for neonatal death. We add to the list of pregnancy complications predicted by an elevated maternal serum α-fetoprotein value increased risks for oligohydramnios (relative risk = 3.4), abruptio placentae (relative risk = 3.0), preeclamptic toxemia (relative risk = 2.3), and premature rupture of membranes (relative risk = 2.0).

Fetal Down syndrome in association with low maternal serum α-fetoprotein levels has been noted repeatedly.[2-4, 12] A New England Regional Genetics Group collaborative study[13] observed that 1:73 women with low maternal serum α-fetoprotein values had a fetus with an autosomal trisomy (virtually all trisomies 21, 18, or 13), a Yale study[4] noted 1:112, and we observed 1:115. For all chromosome abnormalities associated with low maternal serum α-fetoprotein levels, we observed a rate of 1:77, very similar to the odds of 1:67 reported in the New England group study. This and other studies[4, 12] have also documented low maternal serum α-fetoprotein levels in association with trisomy 18 and trisomy 13. In this study a low maternal serum α-fetoprotein value predicted a relative risk of 11.6 for a serious chromosome defect. Unlike others who reported that approximately 50% of spontaneous abortions were associated with low maternal serum α-fetoprotein levels,[10, 14] we noted that only 9.3% of fetal deaths had low values. Variable lower limits for maternal serum α-fetoprotein, study sizes, the population studied, and ascertainment bias probably explain the differences in reported rates.

Consonant with our past experience[6] and that of many others reviewed elsewhere,[1] elevated maternal serum α-fetoprotein values predicted the detection of

100% and 90.9% of anencephaly and spina bifida cases, respectively. Low maternal serum α-fetoprotein levels facilitated detection of 30% (6/20) cases of serious chromosome defects. Utilization of both high and low maternal serum α-fetoprotein values for screening, which to our knowledge has not previously been reported in a prospective study, proved valuable. For all major congenital defects combined, a high or low maternal serum α-fetoprotein value was found in 34.2% of cases. In addition, 19.1% of fetal-neonatal deaths, 11.0% of other listed major pregnancy complications, and 15.9% of other newborn complications were all preceded by high or low maternal serum α-fetoprotein values.

In previous reports reviewed by Wald and Cuckle,[15] and us,[6] that mainly consisted of laboratory experiences rather than systematically collected epidemiologic data, 41% to 64% of multiple pregnancies were associated with increased maternal serum α-fetoprotein values (≥2.0 multiple of the median). Those reports in part reflect results from women selected for screening by obstetricians because of some suspicion of twins or congenital defects. In association with our study we obtained maternal serum α-fetoprotein values on 159 women with multiple pregnancies. Among these women 85 (53%) had maternal serum α-fetoprotein values ≥2.0 multiples of the median.

The proportion of high maternal serum α-fetoprotein values reported here (3.9%) agrees with results of recent studies.[1] Low maternal serum α-fetoprotein values (equivalent to Down syndrome odds ≥1:270) in recent reports have ranged between 2.7% and 5.3%[4, 13]; ours was 3.4%. The frequency of low values is likely to decrease with expected improvements in radioimmunoassay performance, which we have already experienced after completion of this study after changing to a kit with greater precision in the low α-fetoprotein range. This change alone will probably bring greater efficacy to low maternal serum α-fetoprotein screening.

Physicians should be aware of the benefits of both high *and* low maternal serum α-fetoprotein screening, not only in the context of prenatal detection of congenital defects, but also in early identification of women at increased risk of obstetric complications. Chronic villitis and placental vascular lesions are the likely cause of elevated maternal serum α-fetoprotein values in certain cases, especially in association with subsequent intrauterine growth retardation.[16] Hence maternal serum α-fetoprotein screening is indicated even in the patient scheduled for amniocentesis. Care should be taken that blood is drawn *before* the amniocentesis needle is introduced to avoid the frequent and rapid α-fetoprotein leak from the fetal to the maternal circulation after aspiration.

Determination of a normal amniotic fluid α-fetoprotein value and acetylcholinesterase after documentation of an elevated maternal serum α-fetoprotein value provides considerable but far from complete reassurance of fetal normality. Our data[1] and those of Burton[17] indicate that approximately 5% of this group have a fetus with a major congenital defect, such as a cardiac malformation, hydrocephalus, renal abnormality, a limb reduction defect, or multiple congenital anomaly syndrome. Level II ultrasonography should therefore be done routinely in these cases. Consideration should be given to *serial* sonographic study (perhaps a total of three before the twenty-fourth week) to detect hydrocephalus and other evolving defects not yet evident. A fetal echocardiogram should also be considered since the likelihood of a cardiac defect exceeds 1%.[1]

Finally, pediatricians also need to be aware of the potential implications of a history of an elevated maternal serum α-fetoprotein value, considering the relative risks of 4.7 and 3.6 for neonatal death and serious newborn complications, respectively.

We thank the interviewing team, especially Marsha Thomas Lanes, Brenda Flomenhaft, Shirley Kasten, Maryanne Megliola, and Nancy Powell. We are also indebted to the many obstetricians and their staffs for allowing us to study their patients and providing outcome data, and to their many patients who participated in this study.

The efficacy of fetal sonographic biometry in Down syndrome screening

Mark T. Peters, MD, Charles J. Lockwood, MD, and Wayne A. Miller, MD
Lincoln and Boston, Massachusetts

Sonographic biometry has been proposed as a second-trimester Down syndrome screening modality. Approaches have relied on the apparent "shortened" femur length of fetuses with Down syndrome. Unfortunately, significant intercenter variation has been reported in the magnitude of this femur length reduction. In an effort to overcome many of these potential biases and better estimate the magnitude of femur length shortening in fetuses with Down syndrome, a retrospective review of femur length differences between 16 Down syndrome and 194 control fetuses was carried out. All scans were performed by one examiner who used the same equipment and measurement technique. A significant reduction in the observed to expected femur length ratio for a given biparietal diameter was identified in the Down versus control fetuses (0.9574 95% confidence interval 0.9197, 0.9952 versus 0.9999 95% confidence interval 0.9913, 1.0086) ($p < 0.008$). However, the magnitude of this reduction was not sufficient to permit the use of this sonographic approach as an isolated marker for fetal Down syndrome. (AM J OBSTET GYNECOL 1989;161:297-300.)

Key words: Sonographic biometry, shortened femur, Down syndrome screening

Current screening modalities for Down syndrome determine risk on the basis of maternal age and maternal serum α-fetoprotein concentrations. However, this approach fails to identify most fetuses with Down syndrome.[1] Recently several investigators[2,3] have identified differences in sonographically determined femur length measurements between Down syndrome and unaffected fetuses and have proposed its application as a potential screening method. Unfortunately, the discriminatory value of discrepancies in fetal biometry between Down syndrome and unaffected fetuses has not been confirmed by all investigators (Table I).[4,5] Differences in sonographic equipment and measurement criteria may contribute significantly to the observed intercenter variation. Heterogeneity in parental racial-ethnic groups, and therefore in anthropometric indexes, may be present between study and control groups, particularly if the latter are derived from a population at low risk for fetal Down syndrome. These differences are unlikely to be constant across all centers, further exacerbating intercenter variability. When longer ascertainment intervals are used to collect Down syndrome versus control cases, another confounding variable is introduced, since operator experience and equipment resolution will improve over time. Finally,

the subjective tendency to minimize gestational age discrepancies between biparietal diameter (BPD) and femur length measurements also contribute to intercenter variability.

We carried out the following retrospective case-control study in an effort to better define the magnitude of fetal biometric differences between Down syndrome and unaffected fetuses and assess the screening applicability of fetal biometry, free of these biases.

Material and methods

From July 1, 1985, to March 1, 1988, more than 2200 fetuses had an ultrasound scan and amniocentesis performed by a single operator (W. A. M.). The indications for amniocentesis included advanced maternal age, abnormal maternal serum α-fetoprotein concentrations, and a family history of genetic disease. In no case was an amniocentesis carried out because of an abnormal ultrasound finding. All scans included a measurement of BPD and femur length. BPD was measured from the skull's leading edge to leading edge at the level of the thalami. Femur length was determined from the largest single measurement. An ATL 2000 with a 3.5 MHz mechanical sector transducer was used for all ultrasound examinations.

Control group. The control group was obtained by random selection of 194 patients who had undergone genetic amniocentesis and were noted to have normal sonographic anatomy, biometry estimates of gestational age within 1½ weeks of menstrual age, and a normal karyotype.

Study group. Sixteen cases of Down syndrome were identified during the study period. All karyotype diagnoses were made from amniotic fluid cultures, and in no case was the sonographic diagnosis of a fetal congenital anomaly made. In all cases both BPD and femur lengths were recorded and the biometry correlated within 1½ weeks of menstrual age in 13 of 16 cases.

Statistical analysis. Using the method described by Benacerraf et al.,[2] a simple linear regression model of the relationship between femur length and BPD in unaffected fetuses was used to derive expected femur length for a given BPD in both groups. To test the statistical significance of observed differences between case and control populations, unpaired *t* tests and χ_2 were used. Confidence interval estimates for the sensitivity and specificity of observed to expected femur length cutoff points were calculated by the method described by Fleiss.[6]

Results

Comparisons of the mean BPD, femur length, and BPD to femur length ratio at given weeks of gestation were made between the Down syndrome and unaffected populations. Although femur lengths were marginally smaller and the BPD to femur length ratios marginally higher in fetuses with Down syndrome, no statistically significant differences were observed at spe-

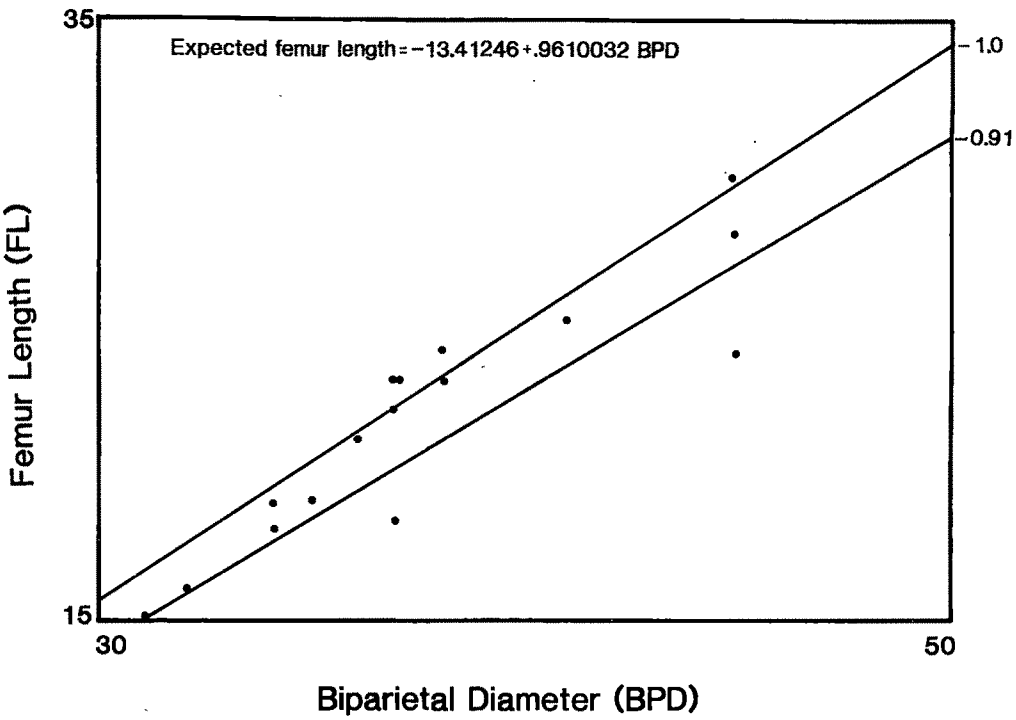

Fig. 1. *Black dots* represent Down syndrome cases. *Top line* is regression line of expected femur length for a given BPD in control group. *Lower line* represents 0.91 of expected femur length for a given BPD.

cific weeks of gestation. The aggregate mean BPD to femur length ratio was significantly higher in the Down syndrome group compared with the control group (1.757 95% confidence interval 1.662, 1.852 versus 1.648 95% confidence interval 1.627, 1.668) ($p <$ 0.004). Only 12.5% (2/16) cases of Down syndrome had a BPD to femur length ratio greater than 1.5 standard deviations above the BPD to femur length mean of the unaffected populations.

The relationship between BPD and femur length in the unaffected population was defined by the following equation: Expected femur length = −13.41246 + 0.9610032 (BPD) (r^2 = 0.883). A first-order regression model proved an optimal description; other regression models did not significantly improve the model.

The expected femur length for a given BPD in the unaffected population is plotted in Fig. 1. The mean ratio of observed to expected femur length for a given BPD was significantly lower in the Down syndrome compared with the control population (0.9574 95% confidence interval 0.9197, 0.9952; n = 16 versus 0.9999 95% confidence interval: 0.9913, 1.0086; n = 194) ($p < 0.008$). Thus for a given BPD, femur lengths of fetuses with Down syndrome were shorter than those of the control group.

Various observed to expected femur length ratio cutoffs were then assessed to determine the efficacy in the identification of fetal Down syndrome cases, which follows the suggestion of Benacerraf et al.[3] The sensitivity, specificity, and positive predictive value of the various cutoff ratios are presented in Table II.

Comment

This retrospective evaluation of sonographically determined biometric differences between second-trimester Down syndrome and unaffected fetus minimizes a number of potential biases present in previous studies. One examiner performed all studies without prior knowledge of the potential for biometric discrepancies in the Down syndrome versus unaffected population. The method of measurement and sonographic equipment used were consistent in both groups throughout the study period. The ascertainment periods were identical in both the study and control populations. The racial and socioeconomic groups were identical in the study and control populations (white, 93% private insurance). Furthermore, single "best" measurements were taken of the BPD and femur length without averaging multiple measurements. These factors should have reduce the potential for subjective reductions in gestational age discrepancies between BPD and femur length measurements.

The lack of statistically significant femur length shortening or elevations in BPD to femur length ratio

at specific gestational age intervals may reflect the small number of Down syndrome cases at given gestational age intervals ($n < 5$). Nonetheless, these observations are in contrast to the findings of Lockwood et al.[2] They first suggested this approach to Down syndrome screening, describing a 50% sensitivity rate and 7% false-positive rate for the detection of Down syndrome fetuses with the use of a BPD to femur length cutoff value of 1.5 standard deviations above the unaffected population's mean BPD to femur length ratio.[2] Implementing an identical approach, only 12.5% (2/16) of fetuses with Down syndrome were identified in this study population with a 7% false-positive rate.

Benacerraf et al.[3] evaluated the Down syndrome screening efficacy of the ratio of observed to expected femur length for a given BPD. They reported optimal screening efficacy with a ratio of 0.91, which produced a 68% sensitivity rate for a 2% false-positive rate.[3] Use of an identical methodology and their optimal cutoff value (0.91) produced a far lower sensitivity rate (13%) and far higher false-positive rate (7%) in this study population. Increasing the false-positive rate to 14% by raising the cutoff ratio to 0.94 afforded an increase in sensitivity to 43%. In contrast, reducing the false-positive rate to 1% by using a cutoff value of 0.86 did not reduce sensitivity (13%).

The finding that there were statistically significant differences between the mean observed to expected femur length value for a given BPD in the Down syndrome versus unaffected population suggests that true biologic differences exist. However, whether these differences are of sufficient magnitude to warrant their use as a screening modality is uncertain. Given that the discriminatory differences in femur lengths (2 to 4 mm) approach the limits of sonographic lateral resolution, far larger numbers of cases and controls must be analyzed to provide a definitive answer. Furthermore, an additional reduction in efficacy can be expected in the prospective application of this modality, since subjective biases will be accentuated. Therefore at this time it does not appear that the detection of a shorter than expected femur length for a given BPD is a sufficient indication for amniocentesis.

One potential value of this sonographic approach is its combination with maternal serum biochemical markers for Down syndrome, such as α-fetoprotein, human chorionic gonadotropin, and unconjugated estriol, as well as maternal age, to assign relative Down syndrome risks to patients as suggested by Wald et al.[7] In this context biometric measurements will either enhance or diminish the risk of Down syndrome without resorting to arbitrary cutoff values, provided they represent an independent measure of Down syndrome risk.[7]

Pregnancy loss in a small chorionic villus sampling series

Brian A. Clark, PhD, MD, John M. Bissonnette, MD, Susan B. Olson, PhD, and R. Ellen Magenis, MD

Portland, Oregon

Two previous reports have suggested that the pregnancy loss rate with chorionic villus biopsy is high in the initial 100 to 300 cases. In the initial 211 cases of this study, the total pregnancy loss rate (7.1%) and losses not attributed to induced abortion or cytogenetic abnormality (2.8%) do not support this contention. (AM J OBSTET GYNECOL 1989;161:301-2.)

Key words: Chorionic villus sampling, fetal loss rate, spontaneous abortion

Chorionic villus sampling promises to rival amniocentesis as a means of prenatal diagnosis if concerns about its safety and accuracy are resolved. The transcervical aspiration of villi at 9 to 12 weeks' gestation offers several advantages over transabdominal aspiration of amniotic fluid at 14 to 16 weeks' gestation for the clonal growth of amniocytes. An anomalous pregnancy at 12 weeks' gestation can be terminated by aspiration with less morbidity than a pregnancy at 17 to 20 weeks' gestation that requires either a dilation and evacuation procedure or the induction of labor.

In two previous reports it has been suggested that the initial experience with chorionic villus sampling is associated with a higher fetal loss rate in small series compared with those with larger numbers of patients. In response to the suggestion that the fetal loss rate did not appear to decline as larger centers gained experience with chorionic villus sampling, Jackson and Wapner[1] stratified their data in accordance with those centers that had experience with 100 to 200 procedures, those with 200 to 300 procedures, and those with >300 procedures. The fetal loss rates were 4.6%, 3.4%, and 2.7% respectively.[1] The report of a World Health Organization symposium on first-trimester fetal diagnosis and risk that pooled information from three groups, revealed a fetal loss rate of 3.4% for the first 300 procedures that declined to 1.7% after ≥400 procedures had been done.[2]

If chorionic villus sampling is to replace amniocentesis as a universal technique for prenatal diagnosis, it not only must be demonstrated safe in large referral center trials, but it also must be demonstrated safe in centers with moderate caseloads. We report on the experience at University Hospital in Portland, Oregon, where 211 chorionic villus sampling procedures have been done over a period of 3.25 years since initiation of the procedure.

Material and methods

Between April 1, 1984, and Sept. 30, 1988, 211 women with pregnancies between 9 to 12 weeks' gestation underwent chorionic villus sampling. An initial ultrasonography scan ruled out fetal death and pregnancies beyond 12 weeks' gestation; these are not included in subsequent analyses. All patients had cervical cultures before the procedure and those with group B streptococci or *Chlamydia* were treated. During the last 6 months of this period women with severely anteflexed uteri had transabdominal chorionic villus sampling (two cases). Initial experience with chorionic villus sampling was obtained in >80 volunteers with noncontinuing pregnancies between 8 to 12 weeks' gestation. All chorionic villus sampling procedures were performed by one of three physicians.

Chorionic villi were obtained under ultrasonographic guidance with a 3.5 MHz real-time sector scanner with a nylon transcervical catheter (ID 1.06 mm). For the majority (167 cases) the CBC-101 catheter (Vas-Cath of Canada Ltd., Mississauga, Ontario) was used. For the remaining 44 cases a Trophocan catheter (Portex, Inc., Wilmington, Mass) was used. Most samples were obtained with a single pass of the catheter. At no time were there more than three passes. A new sterile catheter was used for each individual catheter insertion. All patients have been followed up to at least 28 weeks' gestation and 180 have completed their pregnancies.

Results and comment

The major indication for chorionic villus sampling was advanced maternal age, with 79% of the women ≥34 years old at the time of delivery. A previous pregnancy with a chromosome disorder (11%) or metabolic defect (8%) accounted for the remainder.

A total of nine chromosomal abnormalities were detected, three of which were balanced translocations or

Table I. Pregnancy outcome of 211 chorionic villus sampling procedures

	n	%
Induced abortion	8	3.8
Loss up to 28 weeks' gestation*	6	2.8
Loss after 28 weeks' gestation	1	0.5
Pregnancies delivered or continued beyond 28 weeks' gestation	196	92.9

*Includes one cytogenetic abnormality (45,X).

inversions. This incidence of cytogenetic abnormality (4.3%) is similar to what has been observed in a large series (4.6%).[3] There were three metabolic disorders detected. Two of the chromosome abnormalities were mosaic: 45,X/46,XY and 45,X/46,XY. The former was confirmed both at amniocentesis and at pregnancy termination, whereas the later showed 46,XY in both amniotic fluid cells and in cord blood at birth. In addition to the two cases of mosaicism nine patients went on to amniocentesis—seven because insufficient tissue was obtained at chorionic villus sampling, one because of culture failure, and one because only maternal cells grew. This rate of subsequent amniocentesis (5.2%) can be compared with 9.9% in a series of >1000 women.[3]

Several approaches have been used to evaluate the pregnancy loss rates after chorionic villus sampling. As discussed in a report of a randomized Canadian collaborative clinical trial group, the most meaningful data will include all losses after a viable pregnancy has been determined at 9 to 12 weeks' gestation. The pregnancy outcome from the present series is given in Table I. The total loss rate of 7.1% is identical to that seen in the chorionic villus sampling (7.6%) and amniocentesis (7.0%) groups of the Canadian collaborative trial, each of which involved >1100 patients. The induced abortion rate in our series was slightly higher (3.8% versus 2.2%) and the losses up to 28 weeks' gestation were somewhat lower (2.8% versus 4.9%) than that seen in the chorionic villus sampling group of the Canadian study. If one uses the conventions of the series,* which do not include induced abortions or spontaneous abortions that occurred in cases of cytogenetic abnormalities, our loss rate of 2.8% does not support the suggestion that the pregnancy loss rate is high in the initial 100 to 300 patients.

We thank Drs. John Buckmaster and Kathleen Kennedy for their assistance. We also acknowledge Ms. Keri Stepper for her assistance.

Maternity shelter care for adolescents: Its effect on incidence of low birth weight

Katherine D. LaGuardia, MD, MPH, Maurice L. Druzin, MD, and Carol Eades, BA
New York, New York

A group of 112 pregnant adolescents residing in a maternity shelter was compared with a group of 113 pregnant adolescents residing in their own homes but receiving identical medical care. The sheltered group was made up of a particularly high-risk group: they were more likely to be black, unmarried, receiving public assistance, and registered later for prenatal care than the group living at home. Despite these differences, the sheltered group delivered significantly fewer infants of low birth weight and preterm gestation than the control group. Variables assessed in this study fail to explain this difference. It is concluded that the services offered in a maternity shelter can have a positive impact on the reduction of low birth weight deliveries in a group of high-risk patients. These results indicate that the social and behavioral correlates of low birth weight remain to be fully defined and understood. (Am J Obstet Gynecol 1989;161:303-6.)

Key words: Adolescent pregnancy, low birth weight, maternity shelter

It has been well documented that pregnant adolescents constitute a population at high risk for delivery of low birth weight infants. According to national figures, in 1978, 17% of all births were to teenagers and yet 24% of low birth weight infants had a teenage mother.[1] The relationship between low birth weight and age is a U-shaped curve, with the highest levels occurring under age 20 years and over age 35 years. This relationship has been known for many years and the subject of much discussión in the literature. The reasons for the higher incidence of low birth weight deliveries among adolescents has not been clearly established.

There appear to be two schools of thought in this debate. One maintains it is because of the physical immaturity of the mother,[2, 3] whereas the other maintains that there is an overrepresentation of risk factors associated with low birth weight among young women.[4-6] It is known that young mothers are more likely black, of low socioeconomic status, to report late for prenatal care, and be unmarried.[1] However, when these factors are rigorously excluded from the analysis, there are no demonstrated differences in prematurity or low birth weight rate among infants born to adolescent mothers and those born to women in the 20- to 34-year-old age bracket.[4, 5]

Reprint requests: Katherine D. LaGuardia, MD, MPH, Department of Obstetrics and Gynecology, The New York Hospital–Cornell Medical Center, 525 E. 68th St., New York, NY 10021.

What continues to remain unclear is whether intervention programs for the prevention of low birth weight are effective in populations with these demographic risk factors. Main et al.[7] failed to demonstrate any difference in the incidence of preterm delivery in a controlled clinical trial whose population consisted of indigent black women with a prematurity rate twice the national average. However, others have found intervention programs to be highly effective.[8, 9] It may be that the etiologic factors, which play an important role in producing preterm births in one population and interventions designed to counteract these factors, may not be universally applicable.

We have examined the potential benefits of intensive social services, behavior modification, and heightened awareness of the problems of pregnancy provided in a sheltered environment (a maternity shelter) on the incidence of low birth weight deliveries among a group of indigent urban teenagers. The outcomes of these pregnancies were compared with those of a comparable group of teenagers residing at home but receiving identical medical care. The study was conducted to examine the hypothesis that a model of social and behavioral intervention can reduce low birth weight rates among a group of high-risk patients.

Material and methods

Data for this study were obtained from a retrospective review of 225 consecutive singleton adolescent deliveries that occurred between 1984 and 1986 at The New York Hospital–Cornell Medical Center in New York City. The study group, totaling 112, consisted of all patients 19 years and under who resided at In-

wood House, a maternity shelter for pregnant adolescents, during their pregnancy and at the time of delivery. The control group, totaling 113, consisted of all patients 19 years and under who lived in their communities during their pregnancy and delivery. If a patient did not live at Inwood House, she was placed in the control group. There was no other process of selection. All patients received similar medical care within the prenatal clinic of the Department of Obstetrics and Gynecology at The New York Hospital. Obstetric care was provided by the house staff with faculty supervision. No specific intervention model was used in the clinic.

Inwood House is one of four maternity shelters in New York City. It receives both private and public funding. All patients must be either referred or approved by the Office of Special Services for Children of the Health Resources Administration of New York City. Criteria for admission include age under 21 years and homelessness. Patients are placed in the shelter on a voluntary basis. However, court-ordered placement exists. All residents receive their prenatal care at The New York Hospital, which is located less than one mile from the home. All are given their own room and meals and are required to attend school. Incentives for compliance with clinic appointments, attendance at school, meals, other activities, and meeting curfew are based on a point system developed by the Inwood House staff. Monetary rewards are administered based on an accumulation of points. Each patient is assigned a social worker who is on-site daily at the shelter. Areas of emphasis by the Inwood House staff during the course of a patient's residence include: (1) contraception, (2) reproductive anatomy, (3) preparation for labor and delivery, including signs and symptoms of preterm labor, (4) plans for the infant after delivery, and (5) plans for the mother after delivery.

Gestational age, which is used as a critical variable in testing the hypothesis of the efficacy of this intervention program, was determined by last menstrual period and serial ultrasound studies and then was correlated with a modified Dubowitz assessment in the neonatal period. Infants with more than a 2-week error between the antenatal assessment and the neonatal assessment would have been excluded from the analysis. However, it was unnecessary to exclude any infants on this basis.

Results

A comparison of characteristics of patients in the control and study groups is presented in Table I. The study group was slightly younger, registered significantly later for prenatal care, was more likely to be black, unmarried, and on public assistance than those in the control group. Despite these differences, the study group delivered significantly fewer infants of low birth weight and premature gestation (defined as <37 completed weeks) than the control group. There was no difference in weight gain, incidence of anemia or preeclampsia, or occurrence of preterm labor between the two groups. However, the control group had significantly more smokers than did the study group (35% versus 23%) ($p < 0.05$). Mean birth weight for the study group was 3122 gm and 3082 gm for the control groups. The primary cesarean section rate for both groups was roughly half that of ward patients over age 20 years (12% versus 24.5%).

As presented in Table II, low birth weight rates were 6.2% and 12.4% for the sheltered and nonsheltered groups, respectively (p = NS). When standardized for both birth weight and gestational age, however, the preterm low birth weight drops to 2.6% and 9.7%, respectively ($p < 0.05$). There was no difference in admissions to the neonatal intensive care unit between the two groups.

Incidence of antepartum hospitalization fails to explain the difference in the preterm low birth weight rate between the two groups. As shown in Table III, although the sheltered group spent more days per person in the hospital for preterm labor, the incidence of hospitalization was statistically similar for both groups for all diagnoses.

Comment

The assessment of low birth weight in this study was based on the model of Kaltreider and Kohl,[10] in which low birth weight was defined according to both gestational age and birth weight. Premature low birth weight includes those infants delivered at a gestational age of >20 weeks but less than 37 completed weeks and weighing >500 gm but <2500 gm. The term low birth weight population is defined as those infants born after 37 completed weeks and weighing >500 gm but <2500 gm. Although not entirely accurate, this definition allows separation of the truly preterm infant and the growth retarded infant weighing less than 2500 gm but delivered after 37 weeks.

Although a longer-term, prospective study is necessary to analyze more fully the paradoxic outcome revealed in this study, it appears that the services provided in this particular maternity shelter have a positive impact on reduction of low birth weight in a group of high-risk patients. In particular, the heightened awareness of the staff to the problems of pregnancy and the education provided on the signs and symptoms of preterm labor may have contributed to earlier hospitalization and improved outcome. It is also interesting that significantly fewer study subjects smoked. This finding confirms the beneficial effects of behavior modification in this population.

It may also be that an important component contributing to this improved outcome is a reduction of external stress. Those patients residing in the maternity shelter had external stress largely reduced. They had shelter, food, money, and easy access to health care staff. Those in the control group lived in communities further from the hospital, in variable living conditions, and with financial concerns more complex than those at Inwood House. It appears that the social and behavioral correlates of low birth weight remain to be fully defined and understood. Studies that examine the causal factors of low birth weight in the adolescent population need to assess these correlates.

Fetal hyperinsulinism in anencephaly

C. Hubinont, MD, PhD,* N. M. Fisk, MD, U. Nicolini, MD, and C. H. Rodeck, MD**
London, England

Insulin was measured in the blood collected in utero from three midtrimester anencephalic fetuses. The hyperinsulinism found could be due to an underutilization of glucose in the absence of most of the brain and could be responsible for the relatively normal growth in anencephaly despite the absence of the hypothalamohypophysial axis. (AM J OBSTET GYNECOL 1989;161:306-7.)

Key words: Fetal blood, insulin, anencephalic fetuses

The role of the hypothalamohypophysial system in insulin secretion has been studied previously in humans, as a comparison of normal and anencephalic neonates. Van Assche et al.[1] found normal insulin levels, with hyperinsulinemia being confined to a small subgroup of those with both an intact hypophysis and an abnormal maternal carbohydrate tolerance.

Growth in anencephalic fetuses and newborns has been reported to be normal or slightly decreased despite the absence of growth hormone secretion.[2]

Since fetal insulin is a major determinant of fetal growth and since the insulin status of human anencephalic fetuses in utero has not been reported, we measured plasma insulin levels in fetal blood from midtrimester anencephalic fetuses.

Material and methods

Three fetuses were diagnosed as having anencephaly by ultrasonography at 16, 20, and 24 weeks' gestation (two singleton pregnancies and one twin pregnancy at 24 weeks). Fetal blood was obtained from the affected twin at selective feticide. In the two singleton gestations, fetal blood was aspirated by an ultrasonographically guided needle technique in consenting patients undergoing termination of pregnancy by intraamniotic instillation of prostaglandin E_2.

All three mothers had fasted for 6 to 12 hours. There was no history of maternal glucose intolerance or Rh alloimmunization, both capable of inducing fetal hyperinsulinism.

Insulin assay was performed in duplicate (insulin radioimmunoassay kit, Immunodiagnostics LTD, Tyne & Wear, London). The results were then compared with our normal range, previously established in 33 singleton fetuses (18 to 40 weeks) having blood sampling for prenatal diagnosis of various genetic conditions and later found to be unaffected.

Results

Insulin levels of the three anencephalic fetuses plotted against those of 33 normal fetuses were all higher than the mean + 2 SD for gestational age (Fig. 1).

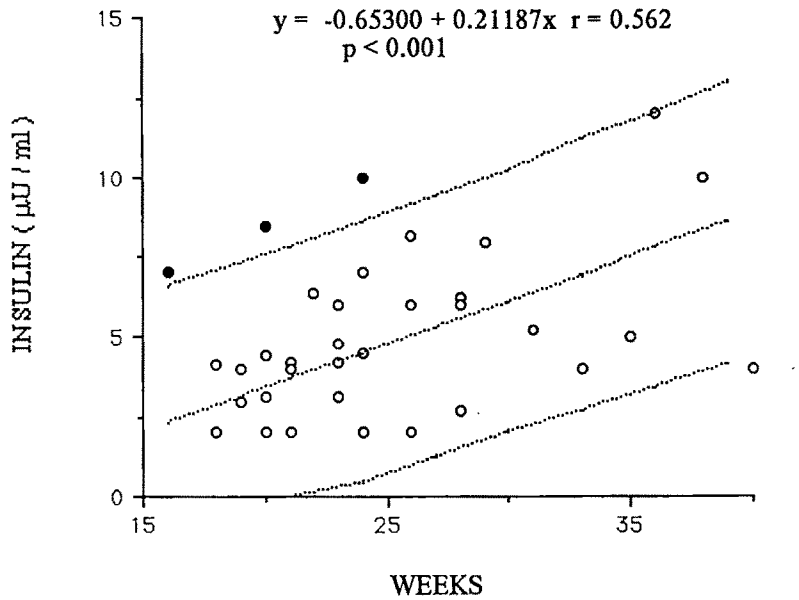

Fig. 1. Plasma insulin concentrations of fetuses with anencephaly(●) plotted against normal values for gestation (○).

Comment

Our finding of hyperinsulinism in anencephalic fetuses differs from the results of Van Assche et al.,[2] but this study was done on newborns whereas our observations were made on fetuses in utero. In fact, the mechanisms of the regulation of insulin secretion in the fetus seem to be different from those in newborns (presence of transplacental transfer of glucose and amino acids), and this may explain the discrepancy in the results.

Hyperinsulinism in anencephalic fetuses might be secondary to high glucose levels, which may be mainly due to underutilization in the absence of most of the brain. Long-term glucose stimulation of the fetal pancreatic β-cells would thus produce hyperinsulinism, as it does in maternal diabetes. Although the features of β-cell stimulation in fetuses of diabetic mothers are usually found only during the third trimester, they have been observed as early as the nineteenth week. This may explain why fetal hyperinsulinism is more marked in the two anencephalic fetuses >20 weeks' gestation.

The presence of hyperinsulinism in anencephalic fetuses suggests that the development and function of their fetal pancreatic β-cells is appropriate, given the increased glucose concentration to which they are probably exposed. Insulin plays an important role in fetal growth; therefore its hypersecretion may compensate for the absence of other growth factors controlled by the hypothalamohypophysial system.

Antenatal ultrasonographic diagnosis of fetal seizure activity

Helain J. Landy, MD, Alfred N. Khoury, MD, and Peter S. Heyl, MD
Washington, D.C., and Fairfax, Virginia

A case is reported in which fetal seizure activity was observed ultrasonographically but the growth-retarded fetus was chromosomally normal. (AM J OBSTET GYNECOL 1989;161:308.)

Two cases of antenatally diagnosed fetal seizures were reported by Conover et al.[1] In both cases, the seizures were associated with anomalous fetuses. We report a case of fetal seizure activity that was observed ultrasonographically in a chromosomally normal, growth-retarded fetus.

Case report

A 35-year-old woman, gravida 2, para 1-0-0-1, was transferred to Fairfax Hospital at 31½ weeks' gestation with intrauterine growth retardation and decreased amniotic fluid volume. A 46,XX karyotype was known from genetic amniocentesis. Administration of α-methyldopa was begun 3 weeks earlier to treat chronic hypertension. On transfer to Fairfax Hospital, an ultrasonogram showed a structurally normal fetus, although the biparietal diameter measured 1½ to 2 weeks less than long-bone and abdominal circumference parameters. The amniotic fluid volume was subjectively decreased. Results of Doppler flow studies of the umbilical artery were normal. Because blood pressure and creatinine clearance values were normal, antihypertensive medication was discontinued. Results of nonstress tests were reactive, and biophysical profiles were normal. Serial ultrasonograms showed good fetal growth, although the discrepancy in biparietal diameter measurement persisted.

During biophysical profile examination at 35 weeks, oligohydramnios was seen. Rapid, repetitive, and episodic jerking fetal movements were noted. These were thought to represent seizure activity. The patient admitted to having felt similar episodes at least once during the preceding week. A reactive nonstress test and negative contraction stress test were obtained.

A live-born female infant was delivered by cesarean section. Seizure activity was evident immediately. Apgar scores were 4 and 8 at 1 and 5 minutes, respectively; the cord pH was 7.32. The newborn's measurements were as follows: weight, 2060 gm; head circumference, 31 cm (10th to 25th percentile); length, 46 cm (25th to 50th percentile for gestational age, Colorado growth curve). A small midline soft palate cleft was seen and the distal clavicles were poorly ossified.

A thorough search for an underlying cause of the seizures was inclusive. Evaluation ruled out infectious causes (adenovirus, coxsackieviruses A and B, herpes simplex virus, echovirus, enteroviruses types 68 through 71, poliovirus, toxoplasmosis, cytomegalovirus, and group B streptococci) and metabolic causes (including lipid storage diseases, endocrinologic disorders, and other imbalances). Results of head and renal ultrasonograms and echocardiogram were normal. The repeat karyotype was 46,XX. The electroencephalogram initially showed a diffuse burst pattern without suppression with pyridoxine, but the abnormalities resolved a few weeks after birth. Phenobarbital was used only for a short time after birth and was then discontinued.

The infant has remained seizure-free without medication. At 10 months of age, she has shown significant growth delay and weighs only 5100 gm. Microcephaly and motor retardation are obvious, and hearing impairment has been diagnosed. A definite underlying cause remains to be confirmed. Serious neurologic handicaps are anticipated for the future.

Comment

Diagnosing fetal seizure activity is quite rare. In the report of two such cases by Conover et al.[1] both fetuses were anomalous (one had multiple subtle anomalies not detectable with ultrasonography and the other had hydramnios and hydranencephaly). In our case no structural anomalies could be identified ultrasonographically, although intrauterine growth retardation, oligohydramnios, and the possiblity of mild microcephaly existed. Knowing that the fetus had a normal karyotype aided in the decision to manage this pregnancy to optimize fetal salvage.

Fetal seizure activity may be associated with metabolic or structural abnormalities, even in the presence of normal ultrasonographic and genetic evaluations. Since this ultrasonographic finding may be associated with a poor outcome, proper counseling is advised.

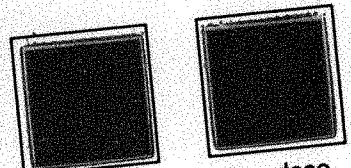
Take the OC preference test.

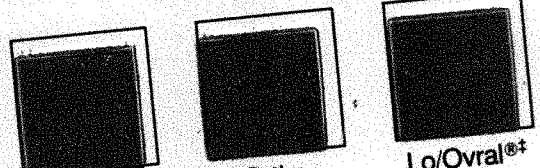
1.



In the United States last year, the OC group with the largest number of prescriptions was:

triphasic | low-dose monophasic | 1/50 formulations

2.



In the last 18 months, more *new* prescriptions were dispensed for:

triphasics | low-dose monophasics

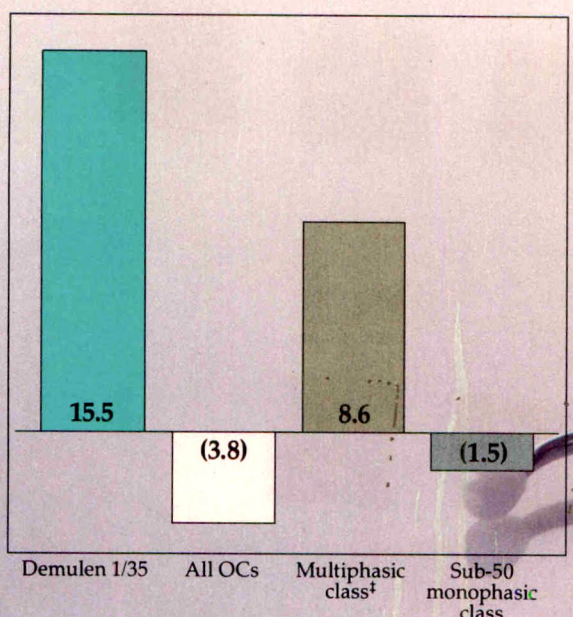
3.

Which monophasic had an increase in new prescriptions 13 times the average of all low-dose monophasics in the last 18 months?

Demulen® 1/35* | Ortho-Novum® 1/35† | Lo/Ovral®‡

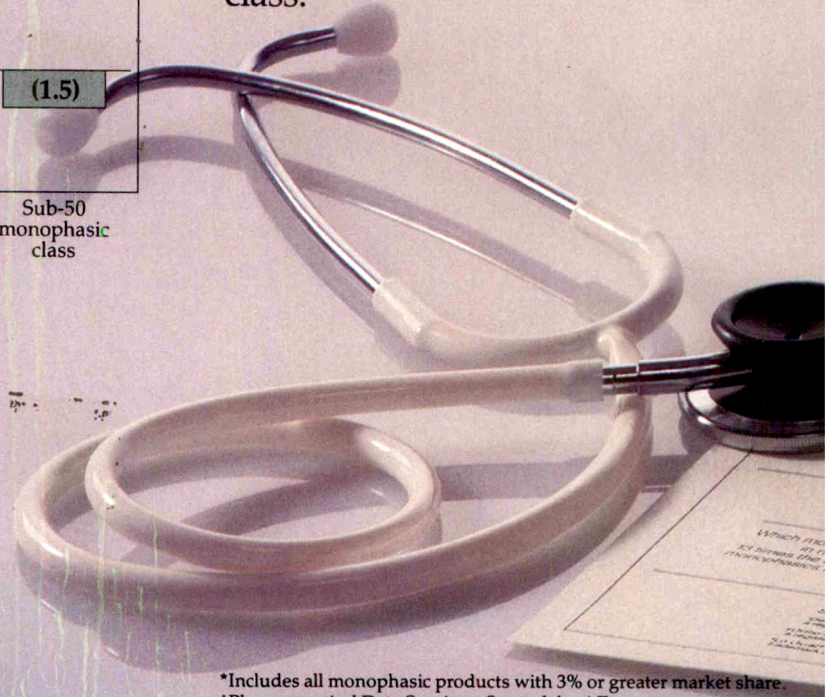
Scratch gold squares with a coin to reveal the answers.

*Demulen® 1/35 (ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg) is a registered trademark of G.D. Searle & Co.



†Ortho-Novum® 1/35 (norethindrone 1 mg, .035 mg ethinyl estradiol) is a registered trademark of Ortho Pharmaceutical Corporation.

‡Lo/Ovral® (norgestrel and ethinyl estradiol tablets) is a registered trademark of Wyeth-Ayerst.

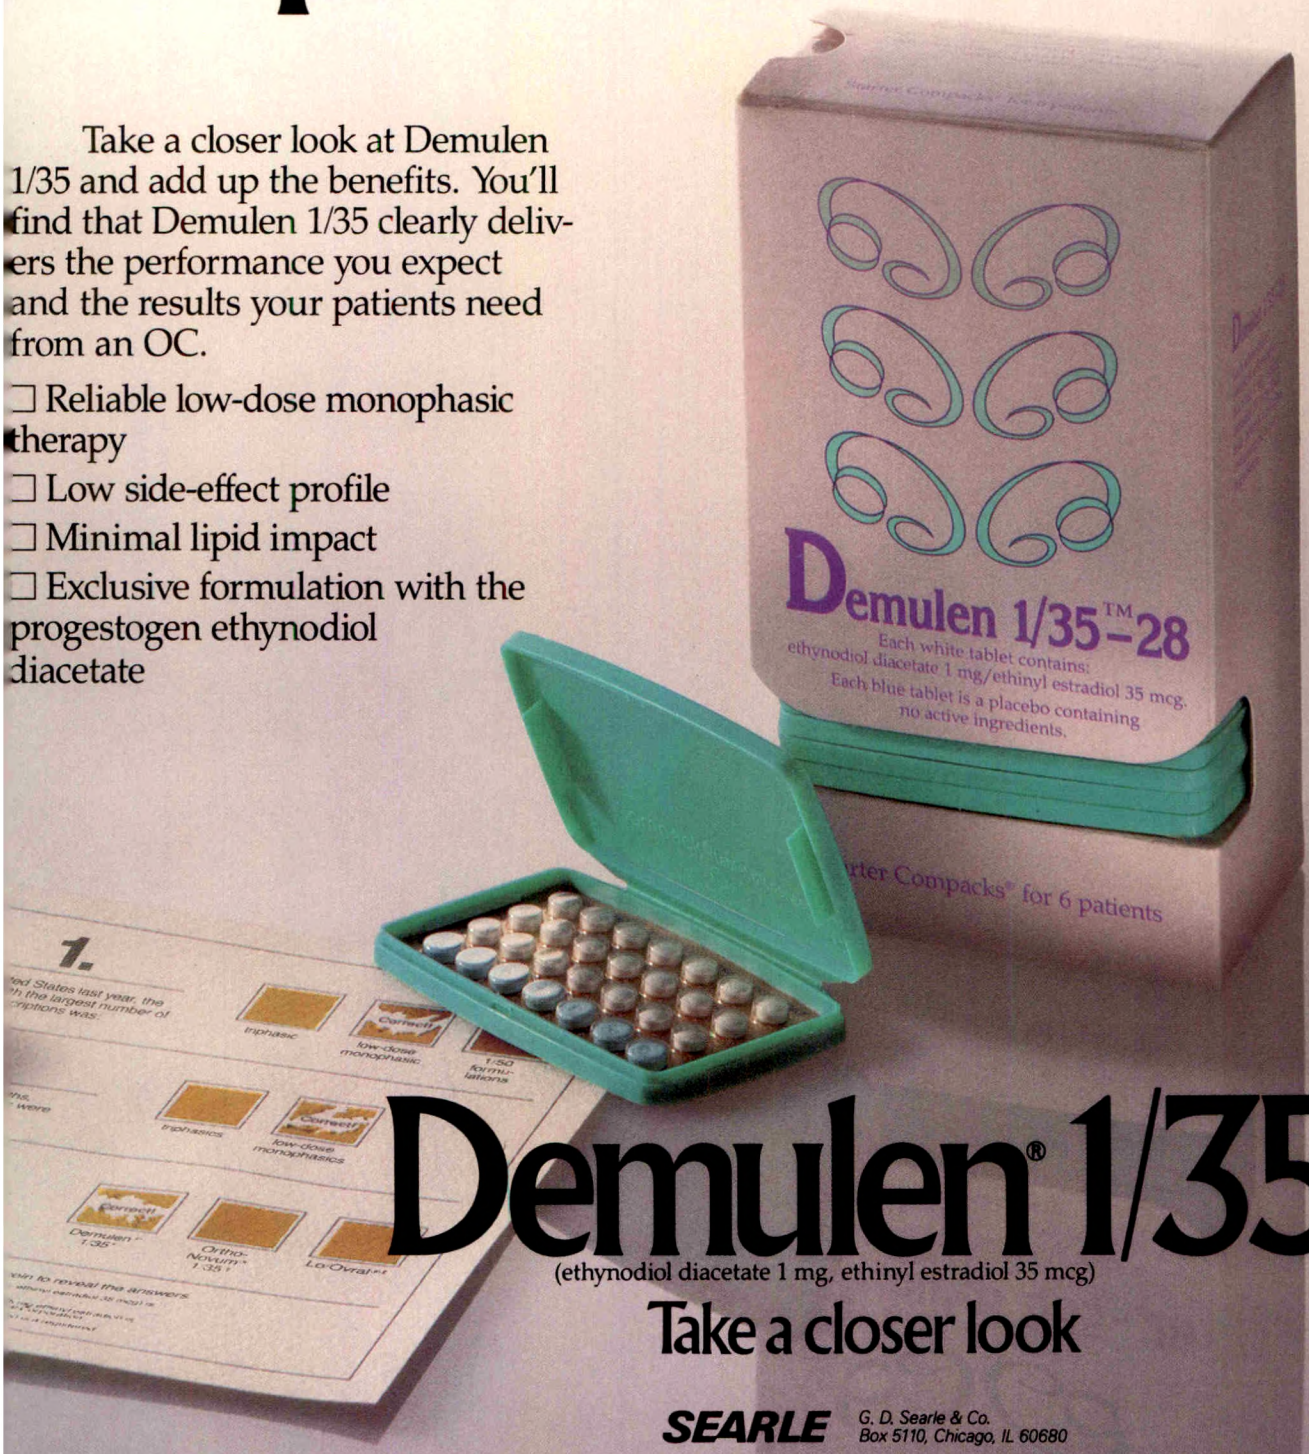


There's an OC ir
and it's not

Now Demulen® 1/35 is the fastest growing monophasic*

New OC Rx's: *Percent change, October 1987 to March 1989*†

Today more and more physicians are taking an increased interest in Demulen 1/35 and prescribing it for their patients on oral contraceptive (OC) therapy. In fact, recent statistics show that new prescriptions for Demulen 1/35 rose by 16% during the last 18 months (October 1987 to March 1989).† That's a significantly greater increase than any other monophasic OC,* and nearly twice the growth rate of the multiphasic class.‡



*Includes all monophasic products with 3% or greater market share.
†Pharmaceutical Data Services, Scottsdale, AZ.
‡Data derived from the change (by percentage) in the number of new prescriptions for all multiphasic products combined, from October 1987 to March 1989.

The physician should become familiar with the full prescribing information (labeling) for this product, which discusses reported risks, such as thromboembolic disorders (including strokes and heart attacks) and hepatic lesions, as well as the need to monitor patients for early symptoms of any diseases or medical conditions, so use can be discontinued where appropriate. A brief summary of the prescribing information accompanies this advertisement.

a growth phase—
a triphasic.

Take a closer look at Demulen 1/35 and add up the benefits. You'll find that Demulen 1/35 clearly delivers the performance you expect and the results your patients need from an OC.

- ❑ Reliable low-dose monophasic therapy
- ❑ Low side-effect profile
- ❑ Minimal lipid impact
- ❑ Exclusive formulation with the progestogen ethynodiol diacetate

Demulen® 1/35

(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

Please see brief summary of prescribing information on following page.

A89-A7450T

Demulen® 1/35

(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

Demulen 1/35™ Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 35 mcg. Each blue tablet in Demulen 1/35-28 is a placebo containing inert ingredients.

Demulen 1/50™ Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 50 mcg. Each pink tablet in Demulen 1/50-28 is a placebo containing inert ingredients. **Indication and usage:** For prevention of pregnancy. Pregnancy rate for products with ≥35 mcg ethinyl estradiol or ≥50 mcg mestranol is ≤1/100 woman-years. With ≤35 mcg ethinyl estradiol, rate is slightly higher; with progestogen-only oral contraceptives (OCs), rate is about 3. Precise comparisons cannot be made. Rates for other methods have been published. *Dose-related Thromboembolic Risk*: Studies showed positive association between OC estrogen dose and thromboembolic risk. It is in keeping with good therapeutics to minimize estrogen exposure. Prescribe product containing least amount of estrogen compatible with acceptable pregnancy rate and patient acceptance. Start new users on ≤50 mcg estrogen. **Contraindications:** Thrombophlebitis, thromboembolic disorders, past history of deep vein thrombophlebitis or thromboembolic disorders; cerebrovascular disease, myocardial infarction or coronary artery disease, or past history of these; known or suspected breast carcinoma, estrogen-dependent neoplasia, or pregnancy; undiagnosed abnormal genital bleeding; past or present, benign or malignant liver tumors developing during use of estrogenic products. **Warnings:**

Cigarette-smoking increases risk of serious cardiovascular side effects from OC use. Risk increases with age and heavy smoking (15 or more cigarettes/day) and is quite marked in women over 35. OC users should be strongly advised not to smoke. OCs are associated with increased risk of several serious conditions including venous and arterial thromboembolism, thrombotic and hemorrhagic stroke, myocardial infarction, visual disorders, hepatic tumors, gallbladder disease, hypertension, fetal abnormalities. Practitioners should be familiar with the available information relating to these and other risks.

1. *Thromboembolic disorders and other vascular problems*: Increased risk of thromboembolic and thrombotic disease associated with OCs is well established. A British study showed increased risk for fatal venous thromboembolism (TE). British and U.S. studies showed increased risk for nonfatal disease. U.S. studies showed increased risk for stroke. OC users were 2-11 times more likely to manifest these diseases without evident cause. In a study of idiopathic deep vein thrombosis and pulmonary embolism (PE), projected hospitalization rates for ages 16-40 were 47/year/100,000 users and 5 for nonusers. Overall excess mortality from PE or stroke was 1.3-3.4 deaths/year/100,000 users and increased with age. *Cerebrovascular Disorders*: In a study of stroke with and without predispositions, risk of hemorrhagic stroke was 2 times greater and thrombotic stroke 4.0-9.5 times greater in users. Mortality trends in 21 countries indicate that changes in cardiovascular mortality were associated with changes in OC prevalence. The Royal College of GPs (RCGP) reported on its prospective study: "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." A 1981 analysis showed a 4-fold increased mortality in users from circulatory diseases, mainly myocardial infarction (MI) and hemorrhagic stroke. Excess mortality was associated with age and smoking. A 1983 analysis showed elevated cerebrovascular disease, increasing with use to 8 yrs, including cerebral thrombosis or embolism and TIA. Peripheral arterial disease and MI were increased. Women over 30 had more arterial disease, being greatest in smokers. Arterial case-fatality was 2-3 times greater for users who smoked. Family Planning Assoc. (FPA) found significant association between OC use and stroke; increased risk for venous thrombosis and PE was 4-fold and statistically significant. Mortality from nonrheumatic heart disease was greater in ever-users. In the Walnut Creek Study, subarachnoid hemorrhage risk was associated with smoking, age, and OC use. *Myocardial Infarction*: Increased risk of MI associated with OCs was reported in Britain, as previously suspected. The morbidity study found the greater the number of risk factors for coronary artery disease (smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk, regardless of OC use. OCs were an additional risk factor. Excess rate of fatal MI was 3.5/year/100,000 users aged 30-39 and 20 for ages 40-44. (These are based on British statistics with acute MI death rates 2-3 times less than the U.S. Similar estimates for the U.S. are 25.7 for users aged 30-39 with predispositions vs 1.5 without; for ages 40-44, 85.2 vs 5.1.) Excess hospitalization rate for nonfatal MI in Britain was 3.5/year/100,000 users aged 30-39 and 47 for ages 40-44. Smoking major predisposing condition to MI. In terms of relative risk, nonsmoking OC users are twice as likely to have fatal MI as nonsmoking nonusers. Smoking users have a 5-fold greater risk than nonsmoking users, but a 10-12-fold greater risk than nonsmoking nonusers. Amount of smoking is an important factor. In determining importance of these risks, give serious consideration to rates in table below. Importance of other predispositions cited above in determining relative and absolute risks has not been quantified; it is likely the same synergism exists, but perhaps to a lesser extent. U.S. studies similarly relate MI, OCs, smoking, and age.

Estimated Mortality Rate from Myocardial Infarction per 100,000 Women/Year

	Aged 30-39:	*Users*	*Nonusers*	*Aged 40-44:*	*Users*	*Nonusers*
All smokers		10.2	2.6		62.0	15.9
≥15 cigarettes daily		13.0	5.1		78.7	31.3
<15 cigarettes daily		4.7	0.9		28.6	5.7
Nonsmokers		1.8	1.2		10.7	7.4
Smokers and nonsmokers		5.4	1.9		32.8	11.7

Risk of Dose: Reports of TE after use of OCs with ≥50 mcg estrogen received by drug safety committees in Britain, Sweden, and Denmark were compared with distribution expected from market research sales estimates. A positive correlation was found between estrogen dose and reporting of TE, including coronary thrombosis, in excess of that predicted by sales. OCs with ≥100 mcg estrogen were associated with higher TE risk than those with 50-80 mcg. Estrogen quantity may not be the sole factor; influence of progestogens was not considered, which may be responsible for certain discrepancies in the data. No significant differences were noted between OCs containing same estrogen dose nor between ethinyl estradiol and mestranol. In Britain certain TE conditions were associated with progestogen or estrogen dose. In Sweden reports of TE decreased when higher estrogen doses were no longer prescribed. Studies on TE risk with progestogen-only OCs have not been done. Cases have been reported for these; they are not presumed free of risk. In a U.S. case-controlled study, relative risk of OC use 1 month before hospitalization for various types of TE was calculated. If relative estrogenic potency and possible influence of different progestogens are ignored, OCs may be divided into those with <100 mcg and those with ≥100 mcg estrogen. For all cases combined, larger doses were associated with only slightly higher risk; for idiopathic cases risk was doubled with larger doses, but confidence limits overlapped and differences were not significant. Apparently there was less increased risk for cases with predispositions. In FPA study no nonhemorrhagic strokes occurred with <50 mcg estrogen, vs 13 with higher doses. TE risk in users and nonusers increases with age. OCs have been considered an independent risk factor. *Persistence of Risk* after OC discontinuation was reported for circulatory disease, nonrheumatic heart disease, and cerebrovascular disease, including subarachnoid hemorrhage, cerebral thrombosis, and TIA. *Excess Mortality from Circulatory Diseases*: A U.K. prospective study estimated annual mortality from circulatory diseases for OC users and nonusers by age, smoking, and duration of use. Excess mortality was 23/100,000 users (2 and 10 for ages 25-34, 15 and 48 for ages 35-44, 41 and 179 for ages >44, for nonsmokers and smokers, respectively). Risk was significant only for smokers over 34. Most deaths were due to subarachnoid hemorrhage or ischemic heart disease. Risk for ever-users rose with parity. One study estimated risk of death with various contraceptive methods, each estimate including risk of method (eg, TE for OCs) plus risk due to pregnancy or abortion in cases of method failure. This latter risk varies with effectiveness. It concluded mortality with all methods is low and below that of childbirth, except for OC users over 40 who smoke. Heavy smokers have double the risk of smokers, light smokers about half. Mortality with OC use in nonsmokers over 40 is higher than with any other method in that age group. Lowest mortality is with condom or diaphragm backed up by early abortion. Risk of TE and thrombotic disease with OCs increases with age after 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia, and especially cigarette smoking. Based on current data, the chart gives gross estimates of risk of death from circulatory disorders associated with OCs:

Risk is: A—very high; B—high; C—moderate; D—low.	Age:	<30	30-39	≥40
Heavy smokers (≥15/day)		C	B	A
Light smokers (<15/day)		D	C	B
Nonsmokers, no predispositions		D	C,D	C
Nonsmokers, with predispositions		C	C,B	B,A

Be alert to earliest manifestations of TE and thrombotic disorders (eg, thrombophlebitis, PE, cerebrovascular insufficiency, coronary artery disease, MI, retinal thrombosis, mesenteric thrombosis). Should any be suspected, discontinue OCs immediately. A 4-7-fold increased risk of postsurgery TE was reported in users; if feasible discontinue OCs at least 4 weeks before surgery or in prolonged immobilization. Before resuming OCs, weigh risks of postsurgery TE complications against contraceptive needs. The RCGP prospective study reported higher incidence of superficial and deep vein thrombosis in users, the former correlated with progestogen dose. The data suggest varicose veins have little effect on development of deep vein thrombosis but substantially increase risk of superficial vein thrombosis, risk depending on severity of varicosities. **2.** *Ocular lesions*: Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OCs. Discontinue if there is unexplained, gradual or sudden, partial or complete loss of vision; proptosis or diplopia; papilledema; or evidence of retinal vascular lesions. Institute diagnostic and therapeutic measures. **3.** *Carcinoma*: Long-term estrogen in certain animals increases carcinomas and/or nonmalignant neoplasms, such as those of breast, uterus, cervix, vagina, ovary, liver, pituitary. Some synthetic progestogens, none currently in OCs, increase incidence of benign and malignant mammary nodules in dogs. There is evidence that estrogens increase risk of human endometrial carcinoma. In case-controlled studies, increased risk (2.2-13.9 times) associated endometrial carcinoma with prolonged estrogen for menopausal symptoms. Risk was independent of other known risk factors and depended on duration of use and dose. This is supported by increased endometrial cancer incidence since 1969 in areas with cancer-reporting systems, which may be related to rapidly expanding estrogen use. There is no evidence that natural estrogens are more or less hazardous than synthetics at equi-estrogenic doses. Of the first 30 case endometrial carcinoma in OC users under 40, those without predispositions (eg, irregular bleeding before OCs, polycy ovaries) occurred nearly always with no-longer-marketed sequential OCs. No statistical association is reported sugges increased endometrial cancer with combination or progestogen-only OCs, though individual cases were reported. Studies sl no increased breast cancer with OCs or estrogens. However, greater risk was noted in OC users with benign breast dise or long-term (2-4 years) use. One study found greater risk of breast cancer with >4 years OC use prior to first full-t pregnancy. Risk of breast cancer with menopausal estrogens rose and further increased with duration of follow-up. OC estrogen were related to breast cancer in connection with other risk factors. Decrease in benign breast tumors in OC user well known. Some studies suggested increased risk of cervical dysplasia, erosion, and carcinoma in long-term users. Cerv microglandular hyperplasia has been reported. In summary, there is no consistent evidence from human studies of increa cancer risk with OCs. Close surveillance is, however, essential. In undiagnosed persistent or recurrent abnormal vag bleeding, consider nonfunctional causes and take diagnostic measures to rule out malignancy. Carefully monitor users strong family history of breast cancer or with breast nodules, fibrocystic disease, recurrent cystic mastitis, abnor mammograms, or cervical dysplasia. **4.** *Hepatic adenomas, etc*, have been associated with OCs. In 1 study OC formulati with high "hormonal potency" were associated with higher risk, as was age over 30. Though benign, these lesions r rupture and cause fatal hemoperitoneum in short- or long-term users. Two studies related risk to duration of use, being m greater after ≥4 years. Long-term OC users have an estimated adenoma incidence of 3-4/year/100,000. Consider s lesions in users with abdominal pain, tenderness, mass, or shock. About 25% present with abdominal masses, up to with acute hemoperitoneum. Radiologic and lab studies may not be helpful; liver scans may show local defect. Hep arteriography or CAT may be useful. Hepatocellular carcinoma risk is increased 7-20 times in users for 8 or more years. duct cancer may occur with OC use. OCs are contraindicated in case of past or present, benign or malignant liver tum developing during use of estrogenic products. **5.** *Use in or immediately preceding pregnancy, birth defects, malignancy offspring*: Estrogens or progestogens during early pregnancy may seriously damage offspring. Females exposed in uterc DES and other nonsteroidal estrogens may have increased risk of vaginal or cervical cancer. Though OCs may not enha this risk, monitor such patients carefully. From 30-90% of DES-exposed women develop benign vaginal or cervical adeno which could be premalignant. DES-exposed daughters have more unfavorable pregnancy outcomes. Males so exposed develop urogenital and sperm defects. Other estrogens may mimic DES. Reports relate fetal exposure to female sex hormo and congenital anomalies, eg, VACTERL for vertebral, anal, cardiac, tracheoesophageal, renal, and limb defects. There appe preferential expression by males. There was a 4.7-fold increased risk of limb-reduction defects in infants exposed in uterc sex hormones (OCs, hormonal withdrawal pregnancy tests, or treatment for threatened abortion). Some exposures were short, being only a few days. Cardiovascular defects in children exposed to female hormones, including OCs, during e pregnancy occurred in 18.2/1,000 births, compared to 7.8 for those unexposed (P<.05). More twinning was reported conceptions shortly after OC discontinuance. Female sex hormones were used for threatened or habitual abortion, but th is considerable evidence estrogens are ineffective and no evidence progestogens are effective. Triploidy and possibly ot polyploidy may be increased in abortuses from women becoming pregnant soon post-OC. These almost always ab spontaneously. It is unknown if spontaneous abortion is increased soon after stopping OCs. Increased chromosome aberratic have been reported. Safety of OCs in pregnancy has not been demonstrated. Rule out pregnancy in using OCs and alwa consider it if withdrawal bleeding does not occur. If 2 consecutive periods are missed rule out pregnancy before continuii If user deviates from regimen, consider pregnancy at first missed period and withhold OCs. If pregnancy is confirmed, appr patient of potential fetal risks and discuss continuation of pregnancy. Users discontinuing for pregnancy should use alternat contraception for 3 months before attempting to conceive, though this is not based on precise information. Do not progestogen-only or progestogen-estrogen drugs as pregnancy tests. **6.** *Gallbladder disease* risk, surgically confirm appeared after 2 years' use and doubled after 4-5 years in 1 study; it appeared in 6-12 months' use in another. **7.** *Carbohydr and lipid metabolism*: Decreased glucose tolerance occurs in a significant number of users; carefully observe diabetic a prediabetic patients. Triglycerides, total phospholipids, and lipoproteins may increase. **8.** *Elevated blood pressure* (BP) occ in some users in a few months, and degree may relate to progestogen dose. Hypertension prevalence in users is not high in the first year, but increases with longer exposure; in the 5th year it is 2½—3 times the first year. Age is strongly correlat with hypertension in users. Those with history of elevated BP (hypertension), preexisting renal disease, history of toxemia elevated BP in pregnancy, familial tendency to hypertension or its consequences, or history of excessive weight gain or fl retention during menstrual cycles may be more likely to develop elevated BP on OCs and should be monitored closely. Ev though elevated BP may be in "normal" range, do not ignore implications. Follow closely, particularly those with other r factors for cardiovascular disease or stroke. High BP may or may not persist after stopping OCs. **9.** *Headache*: Onset exacerbation of migraine or development of headache of a new pattern that is recurrent, persistent, or severe requires stoppi OCs and evaluating cause. **10.** *Bleeding irregularities*: Breakthrough bleeding (BTB), spotting, and amenorrhea are frequ reasons for discontinuing. In BTB, as in all cases of irregular bleeding, consider nonfunctional causes. In undiagnos persistent or recurrent bleeding, rule out pregnancy or malignancy. If pathology is excluded, time or change to another prod may suffice. Change to a higher-estrogen OC only when necessary as this may increase thromboembolic risk. Those w history of oligomenorrhea or secondary amenorrhea or without established regular cycles may be anovulatory or amenorrh after discontinuing. Those with such problems should be so informed and other methods encouraged. Post-use anovulatic possibly prolonged, may occur in women without previous irregularities. Higher incidence of galactorrhea and of pituit tumors has been associated with postpill amenorrhea. One study reported 16-fold increased prevalence of pituitary prolact secreting tumors in patients with postpill amenorrhea when galactorrhea was present. **11.** *Ectopics*: In failures with combinati OCs, the ratio of ectopic to intrauterine pregnancies is no higher than in nonusers. There may be increased risk of ectopi after discontinuing. **12.** *Breast feeding*: OCs may decrease quantity and quality of milk. A small fraction of OC steroids appea in milk. Effects if any on child are unknown. If feasible defer OCs until after weaning. **13.** *Infertility* may occur after discontinui OCs. While impairment diminishes with time, there is still an appreciable difference in nulliparas aged 25-29 after 30 month difference is negligible after 48 months. In nullips aged 30-34 impairment persists to 72 months and is more severe for year users. In paras aged 25-34, difference is negligible after 30 months. **Precautions:** Conduct complete history and physic prior to OC use and annually thereafter. Include breasts, abdomen, and pelvis, with BP, Pap, and lab tests. Preexisting uteri leiomyomata may enlarge. Mental depression may occur; with positive history, observe carefully and discontinue if seriou recurrence. Fluid retention may occur; prescribe cautiously and monitor carefully in convulsive disorders, migraine, asthm or cardiac, hepatic, or renal dysfunction. History of jaundice in pregnancy increases risk of recurrence on OCs; obser carefully and discontinue if it occurs. Cholestatic jaundice occurred after OC and troleandomycin use. OC/cyclospori combination may be hepatotoxic. Steroids may be poorly metabolized in liver dysfunction and should be given cautious Tryptophan metabolism may be disturbed and result in pyridoxine deficiency; megaloblastic anemia has been reported. Seru folate may be depressed and may be exacerbated in post-OC pregnancy. Advise pathologist of OC use when submittir specimens. Endocrine and liver function tests may be altered; repeat abnormal tests after stopping for 2 months. These ha been observed: increased BSP retention and other abnormalities in liver function tests; increased prothrombin and coagulatic factors VII, VIII, IX, X; decreased antithrombin III, increased platelet aggregability; increased thyroid-binding globulin leadir to increased circulating total thyroid hormone (PBI, T_4); decreased T_3 uptake, unaltered free T_4, decreased pregnanedi excretion; reduced metyrapone response; increased blood transcortin, corticosteroid, triglyceride, phospholipid, reduced seru folate; impaired glucose tolerance; altered plasma trace minerals. Influence of prolonged OC use on pituitary, ovarian, adren hepatic, or uterine function, or on immune response not established. OCs may mask onset of climacteric. Cervical chlamydi prevalence is increased; do not assume OC protects against chlamydial PID. *Information for patients*. See patient labelin *Drug interactions*. OC effectiveness may be decreased and more BTB occur with rifampin, isoniazid, ampicillin, neomyci penicillin V, tetracycline, chloramphenicol, sulfonamides, nitrofurantoin, griseofulvin, barbiturates, phenytoin, carbamazepin primidone, phenylbutazone, analgesics, tranquilizers, antimigraines. OCs may alter effectiveness of oral anticoagulant anticonvulsants, tranquilizers, tricyclic antidepressants, antihypertensives, theophylline, caffeine, vitamins, hypoglycemic clofibrate, glucocorticoids, acetaminophen. **Adverse reactions:** Increased risk of the following serious adverse reactions h been associated with OCs: thrombophlebitis and thrombosis; pulmonary embolism; arterial thromboembolism; Raynaud disease, myocardial infarction; coronary thrombosis; cerebral thrombosis; cerebral hemorrhage; hypertension; gallbladd disease; Budd-Chiari syndrome; benign adenomas and other hepatic lesions, with or without intra-abdominal bleeding, liv cancer, congenital abnormalities. There is evidence of association between the following and OCs, though confirmatory studi have not been done: mesenteric thrombosis; neuro-ocular lesions, eg, retinal thrombosis and optic neuritis. The following a believed drug related: nausea, vomiting, gastrointestinal symptoms, BTB, spotting, change in menstrual flow, dysmenorrhe amenorrhea during and after use, infertility post-OC, edema, chloasma or melasma, which may persist post-OC, brea changes (tenderness, enlargement, secretion), weight changes, change in cervical erosion and secretion, endocervic hyperplasia, lactation decrease, cholestatic jaundice, migraine, enlarged uterine leiomyomata, allergic rash, mental depressio reduced carbohydrate tolerance, vaginal candidiasis, change in corneal curvature (steepening), intolerance to contact lense Association not confirmed or refuted for: premenstrual-like syndrome, cataracts, libido changes, chorea, appetite change cystitis-like syndrome, headache, paresthesia, nervousness, dizziness, auditory disturbances, rhinitis, fatigue, backach hirsutism, scalp hair loss, erythema multiforme or nodosum, hemorrhagic eruption, herpes gestationis, hemolytic uremi malignant hypertension, itching, vaginitis, porphyria, impaired renal function, acute renal failure, sometimes irreversible, PVC abnormal EKG, pulmonary hypertension, TTP, anemia, pancreatitis, hepatitis, colitis, Crohn's disease, gingivitis, dry socke lupus erythematosus, rheumatoid arthritis, pituitary tumors (eg, adenoma) with amenorrhea and/or galactorrhea after us malignant melanoma, endometrial, cervical, breast, and bile duct carcinoma. **Acute overdosage:** Serious ill effects have n been reported after large acute doses of OCs in young children. Nausea and withdrawal bleeding might occur. **Important not Complete prescribing information should be consulted prior to use and is available on request.**

Phase II trial of ifosfamide and mesna in mixed mesodermal tumors of the uterus (A Gynecologic Oncology Group Study*)

Gregory P. Sutton, MD,[a] John A. Blessing, PhD,[b] Neil Rosenshein, MD,[c] Guy Photopulos, MD,[d] and Philip J. DiSaia, MD[e]

Indianapolis, Indiana, Buffalo, New York, Baltimore, Maryland, Memphis, Tennessee, and Orange, California

A phase II trial of ifosfamide (isophosphamide, NSC 109724) and mesna (2-mercaptoethane sodium sulfonate, NSC 113891) in women with advanced or recurrent mixed mullerian tumors of the uterus was conducted by the Gynecologic Oncology Group. The starting dose of ifosfamide was 1.5 gm/m^2 daily, intravenously, for 5 days. The starting dose of ifosfamide was reduced 1.2 gm/m^2 daily in patients who had received prior radiotherapy. Mesna was given intravenously immediately and at 4 and 8 hours after the administration of ifosfamide. Each mesna dose was 20% of the total daily dose of ifosfamide. Twenty-nine patients are evaluable for toxicity, and 28 patients are evaluable for response. Twenty-one patients had received prior abdominal hysterectomy, and eight patients had prior radiotherapy. Thirteen tumors were homologous and 15 heterologous. Gynecologic Oncology Group grade 3 or 4 granulocytopenia occurred in seven (25%) patients and two (7.1%) had grade 3 or 4 thrombocytopenia. Two patients (7.1%) had grade 3 or 4 neurotoxicity. One patient experienced lethargy and confusion that responded to discontinuation of the ifosfamide. A second patient developed progressive cerebellar dysfunction, left hemiparesis, and coma. This patient died after 3 days of therapy. Complete responses were seen in five (17.9%) patients and partial responses occurred in four (14.3%) patients for a total response rate of 32.2%. These results indicate that ifosfamide is an unusually active drug in patients with advanced or recurrent mixed mullerian tumors of the uterus. Studies with combination regimens incorporating ifosfamide are warranted. The toxicity of ifosfamide in Gynecologic Oncology Group studies is being evaluated retrospectively. (Am J Obstet Gynecol 1989;161:309-12.)

Key words: Ifosfamide, mesna, mullerian tumors

Although ifosfamide was first synthesized in Germany in the mid-1960s, severe urothelial toxicity prevented widespread evaluation of the drug until the uroprotector mesna (2-mercaptoethane sodium sulfonate) became available. Since the introduction of mesna, ifosfamide has been found to be highly active in the treatment of malignant lymphomas and pancreatic, testicular, and ovarian carcinomas.

With the exception of doxorubicin, ifosfamide possesses unsurpassed activity in the treatment of soft tissue sarcomas. Bramwell et al.[1] compared cyclophosphamide with ifosfamide in advanced soft tissue sarcomas. The response rate in previously untreated patients was 25% with ifosfamide and 13% with cyclophosphamide. Other authors[2] have confirmed response rates of 23% to 65% in previously treated patients with soft tissue sarcomas. Ifosfamide is also active in osteosarcoma and Ewing's sarcoma.

Because of these promising results, the Gynecologic Oncology Group elected to initiate a phase II trial of ifosfamide and mesna in the treatment of patients with uterine sarcomas refractory to surgery and radiotherapy but untreated with previous chemotherapeutic agents. The results of ifosfamide therapy in mixed mullerian tumors are reported herein; results in other uterine sarcomas are pending at this writing.

Methods

Patients with histologically proved advanced or recurrent mixed mesodermal (malignant mixed mullerian) tumors of the uterus not amenable to curative ther-

apy but unexposed to prior chemotherapeutic agents were eligible for this study. Additional eligibility criteria included measurable disease by physical examination or medical imaging technique. Ascites and pleural effusions were not considered measurable disease. Also required were Gynecologic Oncology Group performance status 2 or better (Karnofsky 50-100), an interval of at least 3 weeks since any prior tumor-oriented therapy, absence of significant infection, and recovery from recent surgery or radiotherapy. Adequate hematologic (white blood count $\geq 3000/\mu l$; platelet count $\geq 100{,}000/\mu l$), hepatic (serum bilirubin, aspartate aminotransferase, and alkaline phosphatase $\leq$two times normal), and renal (serum creatinine ≤ 2.0 mg/dl or creatinine clearance ≥ 50 ml/min) function tests. Informed consent was obtained from all subjects, and none was treated until the study was approved by the Human Investigations Committee of the participating institution.

Criteria for exclusion were absence of measurable disease, prior chemotherapy, Gynecologic Oncology Group performance status of ≥ 3, presence of a second malignancy excluding squamous or basal skin lesions, or the presence of microhematuria in excess of the institutional lowest normal range.

Ifosfamide was administered intravenously daily, for 5 days, every 4 weeks, at a dose of 1.5 gm/m^2. This dose was reduced to 1.2 gm/m^2 in patients with prior radiotherapy. Mesna (300 mg/m^2) was given intravenously every 4 hours, for three doses, after ifosfamide administration.

History and physical examination with assessment of evaluable lesions, Gynecologic Oncology Group performance status, blood chemistries, blood urea nitrogen, creatinine, and microscopic urinalysis were performed before each cycle of therapy, and complete blood count, differential, and platelet counts were obtained weekly. Abdominal pelvic computed tomography scans were used unless tumor parameters were assessed by examination or chest radiograph.

Drug administration was delayed after hematologic toxicity until white blood count was $>3000/\mu l$, platelet count was $>100{,}000/\mu l$, and granulocyte count was $>1500/\mu l$. Patients were considered evaluable for toxicity if just one course of therapy was given and evaluable for response after a single course of therapy if there was clearcut progression. In other cases patients remained in the study until disease progression was noted or adverse effects prevented further therapy. Response duration was calculated from the date of response until documentation of disease progression. Standard Gynecologic Oncology Group response criteria were used.[3]

Results

Between May 1986 and March 1988, 30 patients were entered into the study. One never received therapy, which left 29 patients evaluable for toxicity. One patient died during the first course of therapy, leaving 28 patients evaluable for response. The median age of evaluable patients was 68 years (range, 36 to 86 years). Twenty-one patients had undergone prior hysterectomy, one had laparotomy only, and six had no surgery. Eight patients had received prior pelvic radiotherapy. Fifteen patients had heterologous tumors, and 13 had tumors that contained homologous elements.

Response. Table I outlines the clinical results of therapy with ifosfamide. Five patients (17.9%) had complete responses and four (14.3%) had partial responses, for an overall response rate of 32.2%. In addition, 10 patients, or 35.7%, had stable disease. Response duration was 1.4+ to 8.6 months, with a median response duration of 3.8 months. Three patients are progression

free at 1.4, 3.0, and 4.8 months. Response by Gynecologic Oncology Group performance status is shown in Table I. Responses were equally divided between heterologous and homologous tumors. Sites of responding lesions included vagina (four), pelvis (two), lung (two), and suprapubic skin (one). Median age for complete responders was 72 years (range, 36 to 76 years) and 66½ years (range, 63 to 76 years) for partial responders. Only one response occurred in a patient receiving prior radiotherapy; the other eight responders had not received radiotherapy. Complete responders received a median of six courses of chemotherapy (range, five to 16 courses), and partial responders were treated with a median of 6½ courses (range, four to 10 courses). Responses by adverse hematologic effects are detailed in Table II.

Toxicity. Twenty patients were treated at an initial dose of 1.5 gm/m² for 5 days; the remainder had an initial dose of 1.2 gm/m² because of prior radiotherapy. Thirteen patients (46.4%) experienced Gynecologic Oncology Group grade 3 or 4 leukocytopenia (white blood count ≤200/μl), and seven (25%) had granulocyte counts of <1000/μl. The median white blood count nadir for all patients with leukocytopenia was 1700/μl (range, 200 to 3400). White blood count and platelet adverse effects are outlined in Table II. Two patients (7.1%) developed thrombocytopenia of <50,000/μl. The median nadir for patients with thrombocytopenia was 117,000/μl (range, 4000 to 147,000 μl). No patient experienced granulocytopenic fever or thrombocytopenic hemorrhage.

Other adverse effects are listed in Table III. One patient each developed grade 3 or 4 neurotoxicity. The first patient became lethargic and disoriented but responded within 24 hours to the withdrawal of ifosfamide and mesna. A second patient developed cerebellar dysfunction, left hemiparesis, progressive coma, and death during the first course of therapy with ifosfamide and mesna after 3 days. Neurologic evaluation, including a brain computed tomography scan and hepatic and renal function studies, was normal before the patient's death. Lumbar puncture was not performed, and permission for autopsy was not granted.

Hematuria was not observed in this patient population despite prior radiotherapy in many subjects. There was no grade 3 or 4 renal toxicity.

Comment

Although hysterectomy may be curative in a small proportion of patients with early mixed mullerian tumors of the uterus, therapy of these sarcomas has been largely unsuccessful. Reported 5-year survival rates in Stage I disease seldom exceed 50%.[4] Although some authors[5] have recommended adjunctive pelvic radiotherapy in early disease, the benefit of this type of treatment remains controversial.[6] Adjunctive chemotherapy is also unproved; patients with Stage I disease treated with doxorubicin after surgery had no better survival than control subjects undergoing surgery alone in a study conducted by the Gynecologic Oncology Group.[7]

In advanced or recurrent disease, treatment with chemotherapy may produce responses, but they are rarely complete or of long duration. Evaluation of chemotherapeutic agents in mixed mullerian tumors has been hampered because most studies fail to differentiate these neoplasms from other uterine or soft tissue sarcomas. The Gynecologic Oncology Group first demonstrated the differential sensitivity of uterine sarcomas to drug therapy.[8] In this report there was a response rate of 25% in patients having uterine leiomyosarcomas treated with doxorubicin, whereas subjects with mixed mesodermal sarcomas demonstrated only a 15% response rate to the same drug. The addition of dacarbazine to doxorubicin yielded no improvement in either group of patients. Cisplatin has definite activity as a second-line agent in refractory mixed mullerian tumors.

Thigpen et al.[9] reported an 18% response rate in previously treated patients given a dose of 50 μg/m² of cisplatin intravenously every 3 weeks. Two patients developed complete responses and had progression-free intervals of 14 and 16 months. No other single chemotherapeutic agent studied by the Gynecologic Oncology Group has produced results superior to those of cisplatin or ifosfamide.

Combination therapy may produce results more favorable than those obtained with single drugs. Piver et al.[10] reported a 23% response rate, with 12% complete responses, with a combination of cyclophosphamide, vincristine, doxorubicin, and dacarbazine. Hannigan et al.[11] also reported a 29% response rate (13.3% complete) in patients with uterine sarcomas treated with cyclophosphamide, dactinomycin (Actinomycin D), and vincristine. However, there is no current evidence from randomized trials that combination therapy

offers an advantage as single drug therapy in the management of uterine sarcomas.

Ifosfamide-based combination regimens are beginning to show promise in the management of soft tissue sarcomas. This drug has been combined effectively with doxorubicin in phase II studies. Schutte et al.[12] reported a 36% response rate, including 6.3% complete responses in 126 evaluable patients treated with a 1-day regimen of ifosfamide and doxorubicin. Sledge et al.[13] reported that 16 of 39 responders (41%) used a similar regimen. Elias et al.[14] added dacarbazine to these two drugs and observed responses in 13 of 29 patients (45%), with 3 patients or 10% having complete responses. The Gynecologic Oncology Group is currently performing a phase III study using ifosfamide with or without cisplatin in the therapy of advanced uterine sarcomas.

The incidence of neurotoxicity (7.1%) in the present study is lower than that observed by others but may have been underreported in the early portion of this study. Mild neurotoxicity consisting of a decreased level of arousal and somnolence was difficult to detect in the presence of lorazepam, and antiemetic was used frequently during this trial. The person who had progressive confusion and stupor responded rapidly to the discontinuation of ifosfamide. Although lethal toxicity of the central nervous system has been reported after single doses of ifosfamide >3 gm/m^2, this complication is previously unreported in patients receiving doses fractionated over 5 days. Moreover, the pattern of neurotoxicity in the one death in the present study is atypical for adult patients. Most often a decreased level of arousal is noted, although other central nervous system manifestations, such as confusion, hallucinations, forgetfulness, cerebellar signs, weakness, incontinence, and seizures, have been reported.[15] Hemiparesis as an isolated neurologic finding is unreported to the best of the authors' knowledge but may be attributable to exposure to ifosfamide.

The neurotoxicity of ifosfamide is not well understood but may be related to the accumulation of the metabolite chloracetaldehyde. Oxidation of ifosfamide may release 10-fold more chloracetaldehyde than metabolism of similar amounts of cyclophosphamide. This metabolite is related to both acetaldehyde and trichloracetaldehyde, breakdown products of ethanol and chloral hydrate, respectively. Differences in neurotoxicity observed between patients or reported in various trials may be attributable to diverse rates of osfamide administration, variations in hepatic or renal clearance of chloracetaldehyde, or differential sensitivity of the central nervous system to this compound.[16] The Gynecologic Oncology Group is presently reviewing neurologic toxicity among patients treated in a variety of ifosfamide trials to identify factors that may predispose to this side effect of therapy. During treatment with ifosfamide, an effort should be made to minimize concomitant medication with active agents of the central nervous system, such as antiemetics, hypnotics, or antihistamines.

Ceramide lactoside in amniotic fluid: High concentration in chorioamnionitis and in preterm labor

Mikko Hallman, MD, DrMedSci, Kristiina Bry, MD, and Olli Pitkänen, MD
Helsinki, Finland

The mechanisms responsible for the onset and progression of preterm labor are poorly understood. In the present study a total of 115 amniotic fluid specimens were analyzed for a lipid that has not previously been detected in amniotic fluid. This glycolipid was identified as ceramide lactoside. It was found in two-dimensional thin-layer chromatograms for evaluation of lung maturity and quantified by gas chromatography. Ceramide lactoside concentrations in amniotic fluid were low in spontaneous labor at term (1.7 ± 0.7 nmol/ml) and in pregnancies that were not associated with spontaneous preterm labor (1.4 ± 0.6 nmol/ml). The concentrations were high in chorioamnionitis with signs of infection (11.8 ± 5.8 nmol/ml) and in preterm labor without clinical signs of chorioamnionitis (5.4 ± 4.0 nmol/ml). A high ceramide lactoside (≥5 nmol/ml) predicted chorioamnionitis with signs of infection at a sensitivity and a specificity of 94% and 95%, respectively. A moderately high ceramide lactoside concentration (≥2.5 nmol/ml) predicted spontaneous preterm labor: sensitivity, 82%; specificity, 95%. Little, if any, ceramide lactoside was present in urine, vernix, normal fetal membranes, or lung effluent, whereas this glycolipid was present in large amounts in granulocytes and in inflamed fetal membranes. We propose that phagocytosing granulocytes release ceramide lactoside into amniotic fluid. (AM J OBSTET GYNECOL 1989;161:313-8.)

Key words: Preterm labor, diagnosis of chorioamnionitis, amniotic fluid

Preterm birth is the primary cause of neonatal death and morbidity. The identity of the signals involved in the onset and progression of normal and premature labor is still controversial.[1-3] Our deficient understanding of the pathogenetic mechanisms involved has inhibited the development of effective methods to identify high-risk cases or to prevent and treat premature labor. According to the current hypothesis, mobilization of arachidonic acid and synthesis of prostaglandins in fetal membranes play important roles in initiation, propagation, or modulation of human parturition.[4]

Preterm labor is often associated with infection or chorioamnionitis. Bacterial phospholipases have been suggested to release arachidonic acid from the fetal membrane–associated phospholipids and so promote preterm labor.[5] In theory, the inflammatory cells within the fetal membranes could help to precipitate premature labor. During inflammation, products of polymorphonuclear leukocytes accumulate in the transcellular space (for instance, in pulmonary alveolar fluid).[6] This may also apply to the amniotic fluid.

The fetal lung is a source of amniotic fluid phospholipids, which serve as reliable indices of lung maturity. Additionally, amniotic fluid lipids may be derived from fetal membranes, skin, blood, and excretions or from cells in the amniotic fluid. We have recovered amniotic fluid during preterm labor for evaluation of fetal lung maturity. Surprisingly, most of these specimens contained large quantities of a lipid that was identified as ceramide lactoside. We additionally describe the possible source and the concentrations of ceramide lactoside in amniotic fluid in normal and complicated pregnancies.

Patients and methods

A total of 115 amniotic fluid specimens were studied. In 80 cases the specimen was obtained by transabdominal amniocentesis. Fourteen samples were recovered during speculum examination of patients with rupture of the fetal membranes, 17 by amniocentesis during cesarean section, and 4 by amniocentesis after delivery of a fetus with intact membranes. The indications for transabdominal amniocentesis were preeclampsia (13 cases), isoimmunization (9 cases), maternal diabetes (32 cases), premature labor (5 cases), suspected fetal abnormality (12 cases), premature rupture of the fetal membranes (5 cases), and unknown gestational age that was verified by examination of the newborn (4 cases). None of the specimens were visibly contaminated with blood or meconium. The amniotic fluids were centrifuged for 10 minutes at 150 *g*, and the supernatant stored at −20° C before the analysis.

The diagnosis of preterm labor (<37 weeks) was

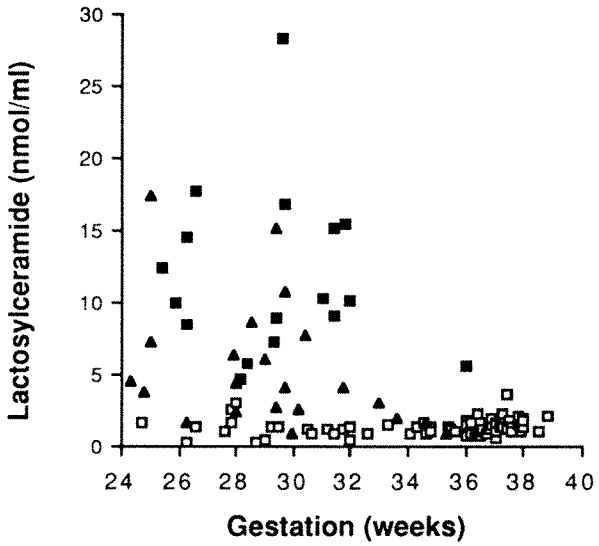

Fig. 2. Concentration of ceramide lactoside in the amniotic fluid. *Open squares*, No preterm labor; *solid triangles*, preterm labor without clinical signs of chorioamnionitis; *solid squares*, chorioamnionitis with signs of infection and preterm labor. None had symptomatic chorioamnionitis without labor.

made when the following symptoms either were present (35 cases)[7] or became evident within 3 days (4 cases): (1) uterine contractions (4 times per 20 minutes or 8 times per 60 minutes) and cervical changes (effacement of ≥80% or dilatation of ≥2 cm) or (2) uterine contractions and rupture of the fetal membranes before 37 weeks. In each case the preterm delivery took place within 0 to 10 days after the specimen was taken.

Chorioamnionitis was suspected when there was rupture of the fetal membranes, when there were signs of infection (maternal fever, elevated C-reactive protein level, leukocytosis, positive maternal cultures), or when the fetal membranes were malodorous and opaque. In these cases the placentas and fetal membranes were examined microscopically by a pathologist. Chorioamnionitis was diagnosed when the fetal membranes, intervillous space, or chorionic plate showed clusters of polymorphonuclear leukocytes (>5 per high-power field) migrating into the chorionic plate on the fetal side of the intervillous space.

The presence of ceramide lactoside in amniotic fluid was verified essentially as described previously.[8] The main features are pointed out briefly here. The lipid was isolated by thin-layer chromatography as a doublet characteristic of ceramide lactoside from extraneural tissues. It contained equimolar quantities of galactose and glucose. According to gas chromatographic analysis,[9] the ratio of sphingosine to glucose and galactose was 1.00:1.05:1.09 (n = 4).

For quantification of ceramide lactoside, the total lipids were isolated by chloroform-methanol extraction, and the glycolipids were "separated" on high-performance thin-layer chromatography plates (Merck, Darmstadt). The chromatograms were developed in one direction with chloroform-methanol–2.5 mol/L ammonium hydroxide, 60:35:8 (vol/vol/vol). Alternatively, we used two-dimensional thin-layer chromatography, as described previously for fetal lung maturity.[10] The lipids were visualized with iodine. Hexose-containing lipids were stained with orcinol in sulfuric acid, and those containing neuraminic acid with resorcinol in hydrochloric acid. The area of the chromatogram that corresponded to the ceramide lactoside standard was stained with iodine and orcinol. It was scraped

Table I. Concentrations of ceramide lactoside in amniotic fluid

Condition	*N*	*Ceramide lactoside (nmol/ml)*	*Gestation (wk)*
Preterm gestation, no labor	52	1.6 ± 0.9	31.6 ± 3.8
Preterm labor, no chorioamnionitis, with signs of infection	22	5.4 ± 4.0	29.5 ± 3.1
Preterm labor, symptomatic chorioamnionitis	17	11.8 ± 5.8	29.3 ± 3.8
Term gestation, no labor	20	1.5 ± 0.6	37.9 ± 0.6
Term labor	4	1.7 ± 0.7	38.2 ± 1.1

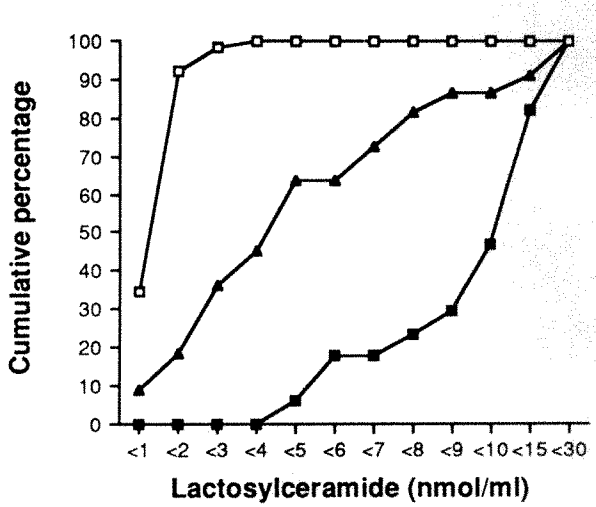

Fig. 3. Percentage distribution of ceramide lactoside concentration in amniotic fluid from preterm pregnancies. *Open squares*, No labor (n = 52); *solid triangles*, spontaneous labor without clinical signs of chorioamnionitis (n = 22); *solid squares*, symptomatic chorioamnionitis and spontaneous labor (n = 17).

from the gel and eluted with chloroform-methanol-water, 5:5:1.1 (vol/vol/vol). The eluate was dried, and the glycolipid degraded in hydrochloric acid–methanol.[8] The carbohydrates released were analyzed with a Hewlett-Packard 5890 gas chromatograph. α-Methylmannoside was used as internal standard. The temperature of the capillary column (cross-linked methyl silicone, 25 m, Hewlett-Packard) was programmed from 80° to 240° C. Hydrocarbons were detected with a flame ionization detector and quantified with a Hewlett-Packard 3390 A integrator. The presence of equimolar quantities of galactose and glucose in all specimens confirmed the specificity of the assay. The concentration of ceramide lactoside was calculated on the basis of the quantity of galactose, which was corrected for the recovery of ceramide lactoside, 69% ± 12%.

The lecithin/sphingomyelin ratio and phosphatidylglycerol were measured semiquantitatively after isolation of individual phospholipids by two-dimensional thin-layer chromatography as described previously.[10] Peripheral blood granulocytes were isolated by density gradient centrifugation and subsequent Ficoll-Paque centrifugation.[11] For isolation of amnion, reflected parts of the fetal membranes were removed from the placentas and washed with isotonic saline solution. The amnion was peeled from the chorion laeve.

The statistical analyses were performed with a Macintosh SE computer and a Stat View 512+ program (Brain Power, Inc, Calabasas, Calif.). Linear regression analysis was used to test whether the concentration of ceramide lactoside was correlated with gestational age. The dependence of ceramide lactoside on additional qualitative factors (sex, complications of pregnancy) was evaluated by multiple regression analysis. The results were expressed as means ± SD. The concentrations of ceramide lactoside were compared by the t test or by the Wilcoxon rank sum test.

Results

Amniotic fluid was recovered from preterm pregnancies or, in some cases, at preterm birth for evaluation of fetal lung maturity and the need of surfactant therapy. The amniotic fluid at term was obtained either during vaginal delivery or during elective cesarean section and used for isolation of human surfactant. Surprisingly, the specimens recovered during preterm labor often contained a lipid, which in the other specimens was either indistinguishable or barely detectable. In two-dimensional thin-layer chromatography the lipid migrated rather closely to phosphatidylglycerol (Fig. 1). In contrast to phosphatidylglycerol, it contained neither phosphorus nor neuraminic acid but stained for hexose.

Specimens of amniotic fluid that contained large quantities of the unknown lipid were therefore developed by one-dimensional thin-layer chromatography for glycolipids, with the appropriate standards. The major glycolipid was identified as ceramide lactoside (see Patients and methods section). It migrates as a doublet, because the fatty acids of ceramide lactoside are not uniform.

An accurate method was designed for quantification of ceramide lactoside, involving both thin-layer and gas-liquid chromatography. The interassay coefficient of variation was 12%. The two-dimensional thin-layer chromatography[10] method is more practical because it allows simultaneous evaluation of both ceramide lactoside and lung maturity.

Fig. 2 shows the concentration of ceramide lactoside in amniotic fluid as a function of gestational age. Table I additionally shows the concentrations of ceramide lactoside in amniotic fluid from term and preterm pregnancies. In pregnancies without labor, the concentrations of ceramide lactoside were low and there were no

Table IIA. Sensitivity and specificity of ceramide lactoside in predicting chorioamnionitis with signs of infection

Table IIB. Sensitivity and specificity of ceramide lactoside in predicting chorioamnionitis in spontaneous preterm labor

Ceramide lactoside	*Preterm labor (n = 39)*		*No preterm labor (n = 76)*		*Sensitivity (%)*	*Specificity (%)*	*Overall accuracy (%)*
	No.	*%*	*No.*	*%*			
≥2.5 nmol/ml	33	84.6	4	5.3	84.6	94.7	91.3

differences between the various diagnostic categories (normal, maternal diabetes, preeclampsia, isoimmunization). Regression analysis showed that there was no significant correlation between the concentration of ceramide lactoside and the length of gestation ($p = 0.078$). In term labor ceramide lactoside was also low. In contrast, during spontaneous preterm labor without chorioamnionitis, the concentration of ceramide lactoside was signficantly higher than in preterm gestation without labor ($p = 0.102$). There was no detectable correlation between the concentration of glycolipid and the length of gestation in preterm labor ($p = 0.102$). The concentration of ceramide lactoside was also high (4.9 ± 1.8 nmol/ml, $n = 4$) in impending preterm labor (labor evident within 3 days after amniocentesis). Both preterm labor in twin pregnancy and "idiopathic" preterm labor were associated with high ceramide lactoside concentrations (6.2 ± 5.0 nmol/ml, $n = 8$; 4.9 ± 3.8 nmol/ml, $n = 14$). The ceramide lactoside concentration was significantly higher in preterm labor with chorioamnionitis than in preterm labor without chorioamnionitis ($p < 0.01$).

For a further study of the factors that influence the concentration of ceramide lactoside, multiple regression analysis was used. In addition to the length of gestation, the influence of the following qualitative factors was studied: fetal sex, isoimmunization, preeclampsia, maternal diabetes, term labor, preterm labor without chorioamnionitis, and chorioamnionitis. Only the last two emerged as significant variables (preterm labor, no chorioamnionitis: $p = 0.002$; chorioamnionitis: $p = 10^{-4}$).

Fig. 3 shows the percentage distribution of ceramide lactoside concentration in amniotic fluid in preterm pregnancy. The group with no labor was entirely different from the group with chorioamnionitis. However, the group with spontaneous labor but no suspicion of chorioamnionitis overlapped with both the other groups.

Tables IIA and IIB show the sensitivity, specificity, and accuracy of ceramide lactoside in predicting chorioamnionitis and preterm labor. The concentration limits for ceramide lactoside were adjusted to attain maximum overall predictive accuracy. Ceramide lactoside was a sensitive and specific index of chorioamnionitis. Its sensitivity in predicting spontaneous preterm labor was 84.6%. The gestational age of the six infants who had low ceramide lactoside concentrations and spontaneous preterm delivery was 31.3 ± 3.7 weeks.

To evaluate the possible source of the glycolipid, the tracheal aspirate, amnion, vernix, urine, and human polymorphonuclear neutrophils were analyzed. In each case cultures of the amniotic fluids and the tracheal aspirates were negative for bacteria. Only the granulocytes, neutrophil-laden fetal membranes, and corresponding amniotic fluids had prominent ceramide lactoside (Table III).

Comment

According to the present study, the concentration of ceramide lactoside in amniotic fluid is strikingly and consistently increased in premature labor during chorioamnionitis. In preterm labor without symptomatic chorioamnionitis, the concentration of ceramide lactoside was higher than in term labor or no labor. These findings suggest that ceramide lactoside in amniotic fluid could be used as a biochemical indicator of the imminence of preterm labor. It is uncertain what the

relationship is between ceramide lactoside and the specific event causing the onset of preterm labor. This issue is important in terms of prevention of spontaneous preterm labor and of detection of high-risk patients.

Ceramide lactoside, consisting of a ceramide moiety and two neutral sugars (galactose-glucose-ceramide), is both a precursor and a catabolic product of neutral glycosphingolipids. The lipophilic ceramide moiety of glycosphingolipids anchors the molecule to the cell membrane, and the hydrophilic sugars may serve as receptors of bioactive agents. Plasma membrane–associated glycolipids play a role in cell-to-cell interaction, differentiation, and growth.[12] Ceramide lactoside, however, forms an exception, being found mainly in intracellular membranes.[13]

Only small quantities of ceramide lactoside, if any, were detected in urine, vernix, bacteria, normal fetal membranes, or lung effluent. However, human granulocytes[13] and the granulocyte-laden amnion found in chorioamnionitis contained large quantities of ceramide lactoside. This glycolipid is additionally released into the supernatant by granulocytes during phagocytosis in vitro (unpublished observations). In neutrophils ceramide lactoside is remarkably abundant.[12, 13] It is therefore possible that in spontaneous preterm labor an increase in ceramide lactoside is indicative of inflammation, although this was not always verified by pathologic examination, since there was no clinical suspicion of chorioamnionitis. However, since there is often no maternal fever in pathologic chorioamnionitis,[14] it is possible that the cases with high ceramide lactoside concentrations actually had pathologic chorioamnionitis without signs of infection. In addition, chorioamnionitis may not be the only inflammatory source of ceramide lactoside. In our series there were two cases of spontaneous preterm labor with high amniotic ceramide lactoside concentrations and an inflammatory disease without pathologic chorioamnionitis: one fetus had funisitis and the other pneumonia. According to present figures the incidence of pathologic chorioamnionitis at term is only 4% to 10%.[14, 15] This is consistent with our finding of low ceramide lactoside concentrations suggesting a paucity of inflammation. The present data do not exclude the possibility that this glycolipid is released from other sources besides inflammatory cells. However, they do imply that preterm labor is associated with a unique enhancement of ceramide lactoside in amniotic fluid.

Bacteria are a source of phospholipases that promote prostaglandin synthesis by releasing arachidonic acid from fetal membranes. Some microbes may have low phospholipase activity,[5] and often no bacteria were cultured in amniotic fluid or fetal membranes in chorioamnionitis. Although microbes are not the only cause of inflammation,[16] there are very few data at present to suggest that nonmicrobial factors[15] are responsible for the onset and progression of chorioamnionitis. In the present study nine amniotic fluid samples were cultured for pathogenic bacteria. Cultures for mycoplasma, frequently found in chorioamnionitis,[15] were not available. Of the six specimens in chorioamnionitis, two were positive for bacteria; both culture-positive (8.7 and 14.4 nmol/ml) and culture-negative (9.9 ± 3.4 nmol/ml) amniotic fluid samples had high ceramide lactoside concentrations.

Table III. Ceramide lactoside in amniotic fluid, lung effluent, and amnion*

	Ceramide lactoside/total phospholipid × 100 (mol/mol)	
	No preterm labor (n = 4)	*Chorioamnionitis and preterm labor (n = 4)*
Amniotic fluid	0.9 ± 0.4	9.9 ± 3.4
Tracheal aspirate at birth	0.4 ± 0.3	0.7 ± 0.4†
Amnion	0.5 ± 0.4	3.0 ± 2.0

*Granulocytes from human blood contained ceramide lactoside (8.9 ± 4.4, $n = 4$), but this glycolipid was not detected in urine or in vernix.

†None of these infants had pneumonia.

The accumulation of ceramide lactoside in the amniotic fluid may in itself have no direct functional importance in the progression of preterm labor but appears to reflect the activity of inflammatory cells. On the other hand, phagocytosis by leukocytes produces other mediators that are potentially important in triggering preterm labor. Granulocytes release arachidonic acid–specific phospholipase A_2 activity and platelet-activating factor.[17] The former conceivably activates prostaglandin synthesis and the latter increases intracellular calcium ions. Phosphoinositide-specific phospholipase C and phospholipase A_2 in fetal membranes,[4] as well as myometrial contractility,[18] are dependent on calcium ions. Second, proteinases released from phagocytosing cells effectively degrade collagen and elastin[6] and may contribute to weakening of the fetal membranes and to biochemical changes that take place during cervical maturation in preterm labor.[18] Finally, the free oxygen radicals formed during phagocytosis may enhance prostaglandin synthesis, promote degradation of collagen, and increase chemotactic substance.[19] The possible role of inflammatory cells and their products as mediators in the onset or progression of preterm labor needs further study.

Cardiac isoenzymes and electrocardiographic changes during ritodrine tocolysis

Hamid A. Hadi, MD, and Sabah J. Albazzaz, MD

Augusta, Georgia

To investigate the potential myocardial ischemic effects of ritodrine, we studied 36 singleton and four twin preterm pregnancies during ritodrine therapy. We serially determined serum creatinine phosphokinase (CPK-MB fraction) and lactic dehydrogenase isoenzymes and performed electrocardiography before and during ritodrine infusion and again within the first 24 hours of oral drug therapy. We observed that serum CPK-MB and lactic dehydrogenase isoenzymes remained within the normal range during therapy periods. The incidence of sinus tachycardia and non-specific T wave changes were 100% and 25%, respectively. In three of four twin pregnancies, ST-T segment depression in leads I, V_4, V_5, and V_6 of the electrocardiogram was noted. Our study suggests that (1) the recommended ritodrine regimen does not produce direct myocardial damage, and (2) ritodrine may cause cardiac ischemia as determined by electrocardiography, which theoretically would progress to myocardial damage if not treated properly. (Am J Obstet Gynecol 1989;161:318-21.)

Key words: Preterm labor, ritodrine, cardiac isoenzymes, electrocardiography

Ritodrine hydrochloride, a β-adrenergic agonist, was approved by the Food and Drug Administration in 1980 and has been widely used in the treatment of preterm labor as a potent tocolytic agent. Its use has been associated with frequent and occasionally severe maternal cardiovascular effects.[1, 2] One of the most im-

portant side effects of ritodrine is potential myocardial toxicity. Animal studies indicate that β-mimetics in dosages not comparable with human dosages result in myocardial ischemia, presumably by causing intracellular adenosine monophosphate depletion.[3, 4] Human studies have reported transient electrocardiographic changes during ritodrine infusion, which also suggests its myocardial ischemic effect.[5] However, at the present time well-controlled prospective data to serially examine changes in sensitive cardiac isoenzymes with simultaneous electrocardiography during ritodrine therapy are lacking. In an attempt to elucidate the myocardial ischemic effect of ritodrine, this study was designed to serially measure serum creatinine phosphokinase (CPK-MB), lactic dehydrogenase subunits (LDH), and LDH_1/LDH_2 ratio and perform electrocardiography before and during ritodrine therapy.

Material and methods

The study was done on 40 patients (36 singleton and four twin pregnancies) undergoing suppression of preterm labor with ritodrine hydrochloride and undertaken after patients signed a consent form approved by the institutional review committee. Maternal age, parity, and race were recorded, and gestational age was determined from patients' last menstrual period or by ultrasound examination. Criteria for enrollment included: (1) preterm labor as defined by regular uterine contractions recurring at less than 10-minute intervals, along with cervical dilation and/or effacement, (2) gestational age between 20 and 36 weeks, and (3) intact membranes. Exclusions from the study included patients with medical complications during pregnancy, such as hypertension, diabetes mellitus, and heart disease.

Ritodrine dosage. Intravenous infusion of ritodrine was administered according to a previously reported protocol.[6] The starting dose was 100 μg/min and increased every 10 minutes by increments of 50 μg/min until labor was inhibited, side effects occurred, or the maximum dose of 350 μg/min was reached. The infusion period was 12 hours, to be followed by 10 mg of ritodrine orally every 2 hours for first 24 hours and then 10 to 20 mg every 4 to 6 hours for subsequent days.

Study periods. There were three study periods: before infusion or control (A), during infusion (B), and oral therapy (C). Serum CPK and MB fraction, total and subunits of LDH isoenzymes, and a standard electrocardiogram were obtained during the preinfusion period and served as patients' own control. These were repeated at 6- and 12-hour intervals during infusion and again within 24 hours of oral ritodrine therapy. An aliquot of blood for CPK isoenzymes was immediately frozen, and isoenzymes were separated by electrophoresis in an agarose medium. Serum samples for LDH subunit (LDH_1 to LDH_5) measurement were collected and stored at room temperature. The cardiac isoenzymes were measured by an automatic clinical analyzer kit (Dupont Company, Clinical Systems Division, Wilmington, Del.). This method is based on a coupled enzyme reaction with the generation of reduced nicotinamide-adenine dinucleotide phosphate, which consists of the Rosalki modification of the original Oliver's assay.[7] The CPK-MB fraction and LDH isoenzymes were interpreted as abnormal if the CPK-MB fraction was >5% and the ratio of LDH_1 to LDH_2 was ≥1.

Maternal systolic and diastolic blood pressures, pulse rate, and serum electrolytes were also measured during study periods. Although the preinfusion period served as the control period, the study was initially designed to use paired *t* tests and compare the mean values of isoenzymes in the infusion and oral periods with those of the control period and consider *p* values <0.05 statistically significant.

Results

Forty patients completed the three study periods. There were 36 singleton pregnancies and four sets of twin gestation. Clinical and laboratory data on study patients are shown in Table I. The results of isoenzyme values during study periods are illustrated in Table II. Total serum CPK, CPK-MB, and LDH isoenzymes re-

Table II. Isoenzyme data on study patients

Isoenzymes (normal values)	*Study periods*			
	A Before infusion	*B During infusion*		*C Oral 24 hr*
		6 hr	*12 hr*	
Total CPK (21-215 mU/ml)	83 ± 15	77 ± 22	89 ± 14	79 ± 18
CPK-MB (%) (0%-5%)	3.1 ± 1.1	3.2 ± 1.3	3.3 ± 1.4	3.1 ± 0.6
LDH_1 (20%-28%)	21	26	25	28
LDH_2 (30%-40%)	32	37	40	40
LDH_3 (18%-24%)	19	23	25	23
LDH_4 (6%-12%)	7	11	12	8
LDH_5 (5%-10%)	6	8	14	13
LDH_1/LDH_2 ratio (<1)	0.6	0.7	0.6	0.7

mained within the normal range during ritodrine study periods. Mean values of CPK-MB isoenzymes during the control periods, 6 and 12 hours of the infusion period, and during oral therapy were 3.1% ± 1.1%, 3.2% ± 1.3%, 3.3% ± 1.4%, and 3.1% ± 0.6%, respectively. Mean values for LDH isoenzymes and LDH_1/LDH_2 ratios were within normal limits. There was no change in mean systolic blood pressure during study periods. However, 18 patients (45%) had a diastolic blood pressure ≤40 mm Hg, including two sets of twins and 10 patients with nonspecific T wave changes on electrocardiography. Serum potassium level declined from a preinfusion rate of 3.5 ± 0.72 to 2.71 ± 0.39 mEq/L during infusion of ritodrine and returned to 3.13 ± 0.02 mEq/L during the oral phase of the study ($p < 0.05$).

Electrocardiographic changes. All patients (100%) had sinus tachycardia during infusion. Ten of 40 patients (25%) had nonspecific (ST < 1 mm above or below baseline) ST-T wave changes during intravenous ritodrine therapy. The QRS axis remained within normal limits throughout the study. In three of four twin pregnancies, significant ST-T segment depression in leads I, V_4, V_5, and V_6 were noted (>1 mm depression). Since the isoenzyme values remained within the normal range during study periods, we did not perform statistical analysis except for comparison of serum potassium values, which showed significant decline during the infusion period.

Comment

Myocardial ischemia has been suggested by the development of chest pain and electrocardiographic changes during β-agonist tocolytic therapy.[5-8] However, controversy exists whether β-mimetics exert a direct cardiotoxic effect or symptoms of ischemia are the result of a fall in mean arterial blood pressure and a shortened diastolic filling time, leading to reduced blood flow to the left ventricular myocardium. These two theories will be addressed in this study.

There is suggestive evidence that as with catecholamines, β-adrenergic tocolytic agents may have cardiotoxic effects. A well-characterized myocardiopathy with subendocardial ischemia has been previously reported in patients with pheochromocytoma.[9] β-Mimetics also produce subendocardial ischemia and necrosis in rats, presumably as a result of an increase in mitochondrial calcium content and depletion of high-energy phosphate stores caused by excessive breakdown of adenosine triphosphate by calcium-dependent adenosine triphosphatase and resultant impaired myocardial oxidative phosphorylation.[10-12] To examine this hypothesis in humans during ritodrine tocolysis, in this study we serially measured total serum CPK, CPK-MB fraction, and LDH isoenzymes. CPK-MB is an energy-transferring enzyme and found most abundantly in high energy–consuming tissues, that is, myocardium. Abundant CPK-MB enzyme level in serum and its rapid release in association with irreversible myocyte injury account for its high diagnostic sensitivity.[13] Serum CPK-MB isoenzyme rises within 4 to 6 hours after chest pain. None of our patients in this series had chest pain, and the CPK-MB isoenzymes during ritodrine infusion and oral therapy remained within the normal range. The LDH isoenzymes appear later than CPK in myocardial infarcts. The ratio of LDH_1 to LDH_2 of ≥1 has become the standard for confirmation of myocardial damage.[13] This ratio remained <1 during our study periods, rejecting the hypothesis of direct myocardial injury with therapeutic ritodrine dosage. Since patients did not have symptoms during the first 24 hours of oral drug therapy and CPK isoenzymes remained within normal limits, we did not extend measurements of LDH subunits beyond this period. Thus we can only categorically state that enzyme studies during the first 24 hours of oral ritodrine therapy did not reveal myocyte damage.

Benedetti[1] and Hankins[14] suggested that β-mimetic–related ischemia appears to be subendocardial in origin. Under physiologic conditions, the ratio of suben-

docardial to epicardial blood flow is 1:1. The combination of pregnancy and β-mimetics diminishes aortic diastolic blood pressure and induces tachycardia, which result in a shortened diastole.

Increased heart rate and myocardial oxygen demands that exceed supply will produce signs of ischemia and may progress to myocyte damage. This intriguing notion is supported by our study, in which a decrease in diastolic blood pressure and electrocardiographic changes, especially in twin pregnancies, were associated with normal cardiac isoenzymes.

In summary, with the use of CPK and LDH isoenzymes and the LDH_1/LDH_2 ratio, this study did not show a direct cardiotoxic effect of ritodrine used for the suppression of preterm labor after a standard protocol. However, manifestations, such as chest pain and electrocardiographic changes, are suggestive of myocardial ischemia caused by ritodrine-related hemodynamic changes, leading to decreased blood flow to the myocardium and may lead to myocyte damage if not properly treated. Increased heart rate and contractility in twin pregnancies compared with singleton pregnancies suggest reduced cardiac reserve.[15] Therefore in the presence of any symptoms of ischemia or electrocardiographic changes, ritodrine should be discontinued. In our institution routine electrocardiography is performed before the administration of ritodrine therapy. Since current ritodrine infusions yield unnecessary excessive plasma concentration and result in significant cardiovascular symptoms, the new low-dose infusion regimen that was recently proposed by Caritis[16] may be beneficial in reducing cardiovascular side effects without adversely affecting the ability of the drug to inhibit labor.

Elevated liver enzymes and thrombocytopenia in the third trimester of pregnancy: An unusual case report and a review of the literature

Mary E. Hannah, MSc, MDCM,[a] Ron Gonen, MD,[a] Eva J. M. Mocarski, MSc, MD,[a] Ross Cameron, MD,[b] Laurence Blendis, MD,[c] and Michael Glynn, MD[c]

Toronto, Ontario, Canada

A woman presented in the third trimester of pregnancy with epigastric pain, elevated liver enzymes, and thrombocytopenia. The frozen-section liver biopsy findings were compatible with acute fatty liver of pregnancy. The light and electron microscopic findings were those of preeclampsia. All clinical and laboratory abnormalities resolved before delivery. (AM J OBSTET GYNECOL 1989;161:322-3.)

Key words: Preeclampsia, thrombocytopenia, acute fatty liver of pregnancy

Acute epigastric pain, elevated liver enzymes, and thrombocytopenia occurring in the third trimester of pregnancy may be a manifestation of preeclampsia, acute fatty liver of pregnancy, or a non-pregnancy-induced liver disorder such as hepatitis. The following is an unusual case in which a transjugular liver biopsy raised more questions than it answered.

Case report

A 32-year-old white primigravid woman was transferred to a tertiary care perinatal unit at 27 weeks' gestation with premature rupture of the membranes and twin gestation. Five days later she developed severe epigastric pain, nausea, and vomiting.

Blood pressure was 110/70 mm Hg, reflexes were normal, and there was no proteinuria. The platelet count was 103 × 10^9/L, serum aspartate aminotransferase 298 U/L (normal <40), alkaline phosphatase 93 U/L (normal <80), and total bilirubin 14 μmol/L (normal <20). There was no evidence of hemolysis. During the subsequent 24 hours, the platelet count fell and the serum aspartate aminotransferase level rose (Fig. 1). To distinguish between acute fatty liver of pregnancy, atypical preeclampsia, or some other liver disorder, a transjugular liver biopsy was performed. Frozen sections stained with hematoxylin and eosin and with oil red O showed many small orangeophilic globules considered to be fat in hepatocytes, compatible with acute fatty liver of pregnancy.

Light and electron microscopic examinations revealed distinctive zone 1 changes, namely, fibrin thrombi filling sinusoids, hepatocytic necrosis, and focal hemorrhages around all portal tracts with minimal or absent fatty change in any zone. This abnormality is characteristic of preeclampsia or eclampsia.

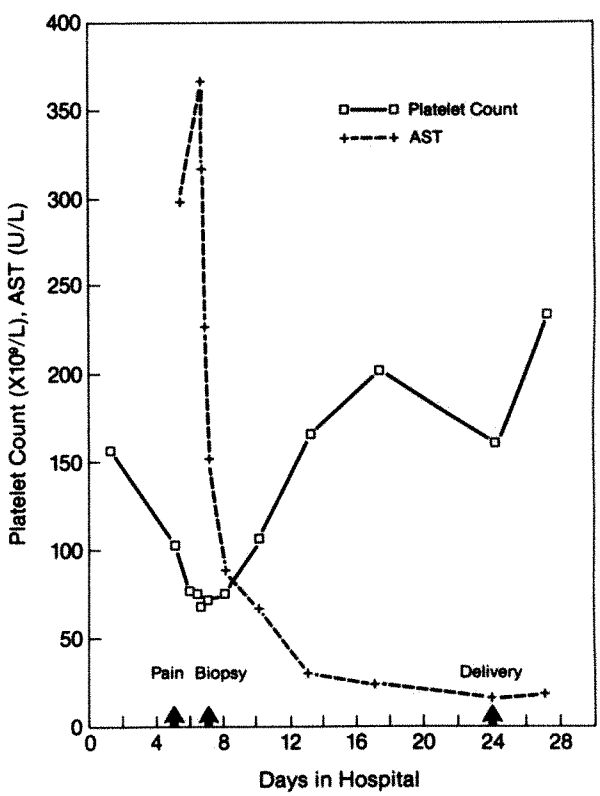

Fig. 1. Changes in serum aspartate aminotransferase *(AST)* level and platelet count during hospital stay.

Laboratory values normalized with expectant management (Fig. 1). On day 26 the patient developed chorioamnionitis and was delivered by cesarean section of two live female infants, weighing 1605 and 1230 gm. The patient and the infants had uneventful postoperative and neonatal courses, respectively.

Comment

The liver abnormalities seen in acute fatty liver of pregnancy and in preeclampsia are considered to be quite distinct. The most characteristic microscopic feature of acute fatty liver of pregnancy is the marked deposition of centrilobular microvesicular fat. This is detected on fixed sections stained with hematoxylin and eosin or on frozen section stained with oil red O. In contrast, in preeclampsia-eclampsia, fibrin deposition, hemorrhage, and hepatocellular necrosis in periportal areas are seen.

Many authors have diagnosed acute fatty liver of pregnancy only on the basis of a frozen section stained with oil red O.

In this case the technique proved to be misleading. The histologic features of the liver on the fixed sections were compatible with those found in preeclampsia. The absence of hypertension, proteinuria, and hemolysis and the spontaneous clinical recovery before delivery make the case unusual. Similar cases, however, have been reported.[1, 2]

It is possible that the "preeclamptic" disorder represents a pathologic continuum and that there are atypical presentations that are self-limiting. It is also possible that these cases are being diagnosed more frequently now by liver biopsy.

The treatment of choice for severe preeclampsia and acute fatty liver of pregnancy remains expeditious delivery. However, when the clinical disturbance is atypical and the fetus preterm, consideration should be given to an expectant management approach, provided that the patient is closely monitored and her condition is stable.

Continuous tissue pH monitoring in the term fetus

Mary L. Small, MD, Marie Beall, MD, Lawrence D. Platt, MD, Diane Dirks, RN, and Howard Hochberg, MD

Los Angeles, California

Since Saling's work in 1961, many investigators have attempted to perfect methods to detect fetal acidosis during labor. A system for continuous tissue pH monitoring of the fetus is evaluated in this study of 59 patients. There was poor correlation of tissue pH values and capillary scalp pH values in 19 cases (r = 0.487), and no significant correlation of tissue pH values to the outcome measurements of Apgar scores and cord gas levels. The benefits realized were those of monitoring the trend of tissue pH over time. We believe that a continuous pH monitoring system offers several advantages over intermittent fetal scalp sampling. Further refinement of the technology employed may offer such a system in the future. (Am J Obstet Gynecol 1989;161:323-9.)

Key words: Tissue pH, fetal scalp pH, fetal monitoring

The advent of electronic fetal monitoring in the late 1960s made it possible for obstetricians to evaluate the fetus in the intrapartum period. Occasionally the analysis of the instantaneous fetal heart rate (FHR) was not straightforward. The search for explanations for variance between FHR patterns and the fetal condition led to development and refinement of methods to detect fetal acidosis, first introduced by Saling in 1962.[1] Obtaining a sample of capillary blood from the presenting part by fetal scalp sampling has gained wide but grudging acceptance. Reasons for lack of universal use of fetal scalp sampling include lack of ongoing experience by the attending obstetrician, discomfort to the patient, technical difficulty in obtaining the sample, and numerous chances for error in performance and interpretation of the test. The physician is generally reluctant to repeat this cumbersome procedure, and this limits the ability to discover trend in the pH.

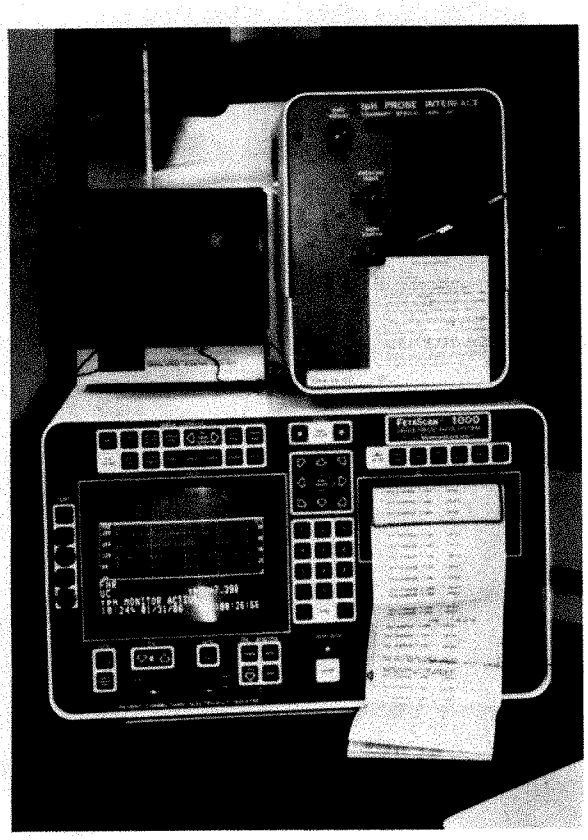

Fig. 1. Fetascan 1000 Obstetrical Data System.

To overcome these difficulties, many investigators have attempted to develop a continuous pH system that initially would determine fetal pH and ultimately be able to measure other respiratory parameters. Objection to some pH systems in the past has concentrated on the use of glass electrodes because of the potential for breakage within the fetal scalp.

This study was undertaken to investigate the use of a new tissue pH (tpH) and fetal monitoring system (Fetascan 1000 Obstetrical Data System, Biomedics International, Bothell, Wash.) that utilizes a spiral needle electrode, similar to the widely used spiral electrode for FHR monitoring. The pH values obtained in our study were to be compared with capillary pH values obtained by fetal scalp sampling to determine if there is a consistent relationship between the two systems. Additionally, the results were to be compared with fetal outcome (judged by 5-minute Apgar score) and cord blood gas levels at delivery.

Material and methods

Study patients were selected from those seen in the labor and delivery area of Women's Hospital at Los Angeles County/University of Southern California Medical Center. Candidates for the study were those patients whose fetuses displayed abnormal or suspicious intrapartum FHR tracings and thus were candidates for scalp pH determinations. After the patient was identified, informed consent was obtained and the patient was prepared for both the traditional fetal scalp sampling and the placement of the tissue pH probe-electrode for use with the tissue pH–FHR monitoring system.

Table I. Characteristics of 59 patients undergoing continuous tissue pH monitoring

	Minimum	*Maximum*	*Mean*
Maternal age (yr)	17	43	26
Estimated gestational age (wk)	35	46	40.7
Duration probe attachment (hr)	0.25	5.5	2.3
Interval between probe removal and delivery (hr)	0.05	11.5	1.6

The monitoring system consists of the following: a combined FHR and tissue pH monitor and a uterine pressure monitor (Fig. 1). The tissue pH is monitored by means of a fiberoptic probe connected by a flexible cable to the tissue pH machine. At the distal end of the probe is a 22-gauge needle formed into a spiral that penetrates into the fetal scalp 3.5 to 4.0 mm (Figs. 2 and 3), just exceeding the usual neonatal scalp thickness (excluding subcutaneous tissue) of 3.0 mm.[2,3] Just proximal to the end of the needle is a window that is covered by a semipermeable membrane through which tissue fluids can pass. The end of the needle under this window is packed with pH-sensitive dye particles of phenol red polyacrylamide.

Changing tissue pH causes a color change in the dye, and this color change is interpreted by the fiberoptic probe as a change in pH. Red and green light passes through the fibers of the cable. Because red light absorbance is not affected by pH in this range, red light reflectance is used to measure probe integrity, and the green light absorbance changes reflect the pH changes. The tissue pH machine provides a continuous printout representing every-1-minute updated pH measurements (Fig. 4). In addition to fetal heart rate and uterine contractions, tissue pH is displayed on an oscilloscope screen.

The probe was sterilized by immersion in activated glutaraldehyde (Omnicide, American Hosp. Corp., McGaw Park, Ill.) for at least 10 hours before each use. To date this equipment has been designed to be reusable with proper cleaning and resterilization between cases. Before application, the sterile probe is calibrated in pH 7.00 and pH 7.40 buffer solutions kept at 37° C in a heating block. This calibration requires approximately 30 minutes.

The spiral probe is applied to the fetal scalp with the

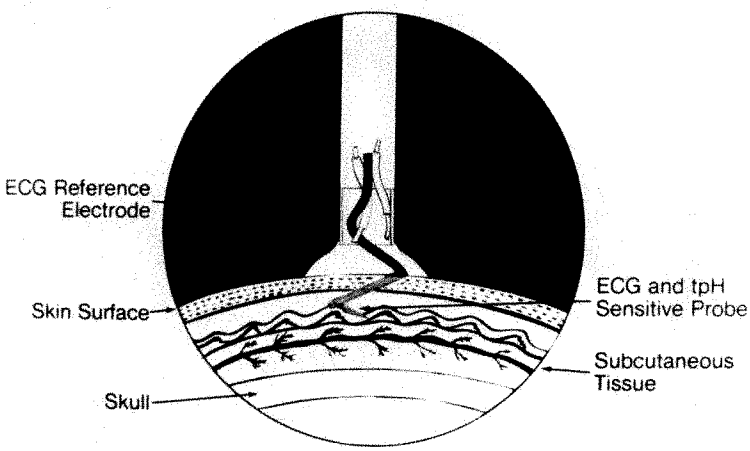

Fig. 2. Diagram of fiberoptic tissue pH probe in situ.

aid of a plastic applicator tool similar to the guide tube used for ordinary scalp electrodes. The two types of electrodes are compared in Fig. 3. On insertion of the probe into the fetal scalp, a fetal electrocardiogram is obtained and integrated into the electronics of the system that serves as FHR monitor and tissue pH monitor. Uterine contractions can be monitored by either an external tocodynamometer or an intrauterine pressure catheter connected to the tissue pH machine. Probe applications were done by three of the authors (M. S., M. B., or L. D. P.) on most of the patients, whereas fetal scalp sampling was usually done by the house staff on duty. The calibration and monitoring were done by the research nurse (D. D.) or by one of the other authors.

After the system was applied and a stable pH reading was attained (approximately 10 minutes), fetal scalp sampling was performed. One specimen was tested immediately for pH on the machine in the labor room (Corometrics 220, Corometrics Medical Systems, Inc., Wallingford, Conn.). An additional one to three specimens were sent to the blood gas laboratory for pH, Po_2, Pco_2, and bicarbonate determinations, completed by the blood gas analyzer method. Acceptable data pairs were those in which fetal scalp sampling was done during the tissue pH monitoring period and in which the tissue pH values were between 7.09 and 7.44 (the values defined as the limits of reliability of the machine). In most cases the patients were monitored until they were transferred to the delivery room. In the delivery room cord samples were obtained immediately after delivery for additional blood gas and pH determinations.

After the probe was removed, a drift check was done to compare the prestudy and poststudy response of the probe to pH 7.00 and 7.40 buffers. If the drift check for probe stability deviated by more than 0.04 pH unit, the probe was considered unstable and data collected with it were discarded.

The newborn infants were examined in the nursery on the second or third day for signs of scalp infection, laceration, or other injury as a result of the tissue pH monitoring.

In analysis of the data, tissue pH and capillary pH values were compared with each other in matched samples, and tissue pH was compared with several outcome measures. Pearson's correlation coefficient was calculated for each comparison with an Epistat statistical package (Gustafson, Round Rock, Tex.); $p < 0.05$ was required for significance.

Results

Fifty-nine patients were studied during a 14-month period between November 1984 and March 1986. The mean patient age was 26 years and the mean gestational age was 40.7 weeks (Table I).

In 39 of the 59 cases, satisfactory simultaneous capillary pH–tissue pH data points were obtained. The other 20 cases were unsuccessful because of technical problems discussed below. The scatterplot of these 39 cases (93 points) is shown in Fig. 5, with $r = 0.188$. Comparison of capillary pH with tissue pH showed an algebraic difference ranging from 0.002 to 0.351 (mean, 0.126); tissue pH was lower in all but five cases.

Correlations were then made between tissue pH and various outcome parameters (Table II) that had valid measurements in all 39 cases. However, only one significant correlation was found, between 5-minute Apgar score and the last tissue pH value when tissue pH was obtained within 30 minutes of delivery. Twelve newborns had 1-minute Apgar scores ≤ 7; one of these had a 5-minute Apgar score <7.

Because of the wide range and poor overall correlation between the simultaneous capillary pH–tissue pH data points (Fig. 5), more detailed analysis was done of the data to exclude the less reliable measurements. Data points were excluded if capillary pH–tissue pH

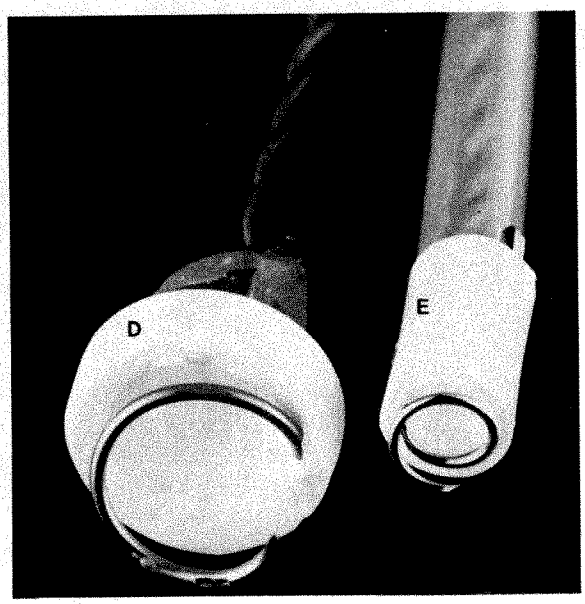

Fig. 3. Comparison of tissue pH fiberoptic probe *(D)* to electronic fetal monitoring scalp electrode *(E)*. (Original magnification ×9.)

pairs were not within 1 minute of each other, if the tissue pH reading had not been stable for 2 minutes before and 2 minutes after the reading was taken, or if capillary pH values were obtained from the labor room pH machine. When exclusions were made for these additional reasons, only 19 pairs of capillary pH–tissue pH data remained that were thought to be reliable points for final statistical analysis. In this group the correlation of capillary pH–tissue pH was $r = 0.487$, $p < 0.05$ (Fig. 6). By comparison, the capillary pH–capillary pH correlation for simultaneous specimens tested in the blood gas laboratory was $r = 0.811$, $p < 0.001$ (Fig. 7).

Follow-up of neonates showed one infant with erythema of the probe puncture site and two infants with scabbing. No neonatal fever or scalp abscesses were noted.

Comment

Because many obstetricians are reluctant to use fetal scalp sampling because of its inconvenience for both doctor and patient, the search continues for a means of continuous pH monitoring in cases in which FHR patterns are suspicious for fetal compromise and the fetal acid-base status needs to be assessed.

From this study it is seen that correlation between continuous tissue pH and capillary pH was modest at best ($r = 0.487$), even when the data were refined to the optimal data pairs. In searching for an explanation of this relatively low correlation, it must be acknowledged that there is a lag time of approximately 6 to 13 minutes between a change in capillary blood pH and the corresponding change in tissue pH, although there is no delay in recording the new tissue pH. This lag is inherent in the design of the machine. Since it is not a constant length of time, it is difficult to assign the appropriate tissue pH for a particular fetal scalp sampling specimen. The relationship between FHR patterns and tissue pH trends has not yet been studied.

When the fetal scalp sampling cone was applied to the fetal scalp, it was often noted that there was an FHR deceleration. It is possible that this FHR change temporarily affected the capillary pH value, such that capillary pH–tissue pH correlation would not be a true measure of the fetal condition. Additionally, an immediate drop in tissue pH was sometimes observed, thus making simultaneous comparison of capillary pH and tissue pH suspect.

It would be reassuring if the difference between capillary pH and tissue pH were constant, which would allow calculation of capillary pH from tissue pH. However, the range of capillary pH–tissue pH difference is too wide in this study (0.002 to 0.351) to be reliable.

Eight probes provided valid data on more than one case each, but since the capillary pH–tissue pH difference between multiple uses of the same probe is greater than the average capillary pH–tissue pH difference (0.126) among cases, this seems to indicate that there is no advantage in using a probe more than once. It would be functionally easier to use a presterilized disposable probe.

Table II shows the lack of correlation between last recorded tissue pH and the outcome variables of Apgar score, umbilical artery pH, and umbilical vein pH. When the cases were limited to those infants who were delivered within ≤30 minutes or ≤15 minutes from probe removal, all variables except last tissue pH versus 5-minute Apgar score showed the same lack of correlation. The explanation for this could be that the in-

Table II. Comparison of last tissue pH with outcome measures

Table III. Usefulness of continuous tissue pH monitoring in seven cases

Case No.	*Benefit*
1	Detected steady downward drift
2	Extra fetal scalp sampling was avoided
3	Despite normal FHR, tissue pH showed steady downward trend
4	Variable decelerations; tissue pH trend allowed labor to continue
5	In presence of tachycardia, tissue pH revealed stability of fetus
6	Tissue pH trend led to repeat fetal scalp sample
7	Trend was helpful

Table IV. Technical objections to fetal scalp sampling

1. Requires cervical dilatation of 3-4 cm
2. Usually done with patient supine, a position not optimal for uteroplacental perfusion
3. Uncomfortable for patient and awkward for personnel
4. Time-consuming
5. Multiple opportunities for error in specimen collection and transport:
   - Inadequate sample because of poor capillary flow or poor technique
   - Air bubbles in capillary tube
   - Contamination with amniotic fluid
   - Inadequate contact of capillary tube with ice in transport
   - Delay in getting specimen to laboratory, with resultant temperature change

terval from probe removal to the outcome measurement was long enough that metabolic readjustment had already occurred. For this reason a system that allows continuous monitoring until the moment of delivery is essential and is currently being developed. However, with the present state of technology the inconvenience of monitoring until delivery (i.e., having to transport the apparatus to the delivery room) restricts the investigation of correlations to Apgar scores or cord blood gas levels. An alternative is to have labor and delivery in the same room, which is being done in many centers.

A further limitation of the system is the necessity to reject tissue pH values <7.09. This has been designated as the lower limit of reliability of the machine and can be a problem if pH values in the fetus are very low, especially if the fetus is acidotic at the time of probe application.

Sixty-two probes were calibrated during the study period. Some of the calibrated probes could not be used because of technical problems, and other probes were substituted. User-related problems included a probe that became loose or fell off, broken cables, recalibration of the machine by mistake, dislodgment of the probe by the fetal scalp sampling cone, unplugging of the machine (which caused loss of calibration), and difficulty in removing the probe from the fetal scalp. There were also certain system-related problems that included the following: repeated gain sets required during a study, leakage of fluid at the Y-joint of the cable, migration of the probe application site posteriorly under the edge of the cervix, slow stabilization of the probe, bent probe, unstable heat block, necessity to recalibrate the probe, and refusal of the machine to display fetal electrocardiogram or tissue pH.

Twenty probes were used in more than one case after appropriate resterilization. In three cases more than

Table V. Detection of acidosis

	Capillary pH acidotic (<7.20)	*Capillary not acidotic (>7.20)*
Tissue pH acidotic (<7.17)	100% Sensitivity	22% False positive
Tissue pH not acidotic (>7.17)	0% False negative	78% Specificity

one probe was used because of difficulty in calibration, placement, or recording of the tissue pH. Eight probes provided valid data on more than one case each.

The 40 cases excluded from final analysis reflect the complexity of this monitoring system. These problems are being addressed, and in the future it is anticipated that there will be precalibrated, sterile, disposable probes that provide automatic drift checks after the studies.

Despite the many difficulties, continuous tissue pH monitoring was considered helpful in patient management in seven cases (Table III). Results of tissue pH monitoring led to repeat fetal scalp sampling in one case, and in four cases a stable tissue pH reassured the physicians about the stability of the fetus and thus avoided extra fetal scalp sampling or premature or unnecessary cesarean section. Each of the fetuses had a 5-minute Apgar score >6. A system of continuous tissue pH monitoring can avoid the multiple opportunities for error inherent in repeated fetal scalp sampling with its isolated data points (Table IV). It also allows the laboring patient to remain on her side while pH monitoring is being accomplished, a feature not always preferred by persons doing fetal scalp sampling with the cone but one that is important in optimizing uteroplacental perfusion.[4]

After collation of data from several centers involved in studying the Fetascan 1000 monitor, one author (H. H.) found that tissue pH was consistently 0.03 pH unit lower than capillary pH. Because of this offset the boundary between acidotic and preacidotic states can be shifted downward from 7.20 to 7.17.[5] With these criteria the Fetascan 1000 model detects acidosis with 100% sensitivity and 78% specificity (Table V).

It seems likely that tissue pH monitoring will have its own unique value, not necessarily that of fetal scalp sampling. We believe there are enough advantages to a continuous monitoring system to warrant pursuit of the technical improvements necessary to make it rapid to apply and convenient to use (Table VI). Our recent experience with a modified system supports this position.

Table VI. Comparison of continuous tissue pH to intermittent fetal scalp sampling

Advantages of tissue pH	*Disadvantages of tissue pH*
Minute-by-minute update	Fetal head can change position relative to cervix and dislodge tissue pH probe
Shows trend in tissue pH	Time lag 6-13 min (90% response in 4 minutes)
Can afford an early warning of problems	No large data base of tissue pH measurements compared to fetal outcome
Problems during monitoring will be advised on screen	
Can apply probe to patients whose cervical dilatation does not allow fetal scalp sampling	
Patient can remain in optimum position without disturbing tissue pH monitoring	
Not affected by presence of amniotic fluid	

This study was part of a multicenter trial of the equipment described; further reports of the same apparatus are anticipated.

In conclusion, a study of 59 patients who had continuous tissue pH monitoring showed poor correlation of capillary pH–tissue pH, no correlation of tissue pH with outcome measures, and absence of significant morbidity for fetus or mother. It was helpful in patient management because it revealed trends in tissue pH. With certain technologic improvements it can be a useful tool when it is desirable to know the pH of the fetus.

We thank Paul Roby, MD, for his help in statistical analysis of the data.

Noninvasive management of isolated bilateral fetal hydrothorax

Leen Pijpers, MD, PhD, Annette Reuss, MD, Patricia A. Stewart, NDCT, CCPT, and Juriy W. Wladimiroff, MD, PhD

Rotterdam, The Netherlands

Fetal outcome was studied in eight cases of isolated bilateral fetal hydrothorax. All patients were referred because of polyhydramnios. Spontaneous resolution of pleural effusion was observed twice. No remarkable change in the degree of hydrothorax was demonstrated in the remaining six cases. All eight cases resulted in the birth of a live infant without other abnormalities. Postnatal intubation, which was carried out in all six fetuses with hydrothorax, was always followed by spontaneous respiration. Subsequent thoracocentesis resulted in the collection of 50 to 500 ml of serous fluid. Sustained intubation (7 days) was necessary in only two infants because of developing respiratory distress as a result of prematurity or recurrent pleural fluid accumulation. All eight infants were alive and well at the age of 1 month. Although in the present study noninvasive management of isolated fetal hydrothorax seems to have been justified, a larger multicenter study is needed to compare survival with and without pleuroamniotic shunting. (Am J Obstet Gynecol 1989;161:330-2.)

Key words: Ultrasonography, isolated fetal hydrothorax, polyhydramnios

Bilateral fetal hydrothorax is a pathologic finding that usually occurs as a part of fetal hydrops. Occasionally, however, it may be observed in an isolated form.

A relationship between pleural effusions and the development of lung hypoplasia has been suggested in various reports; the principal goal of thoracocentesis and pleuroamniotic shunting is normal pulmonary development.[1-5] In the fetal lamb progressive inflation of an intrathoracic balloon from a gestational age of 100 days resulted in respiratory insufficiency at birth caused by pulmonary hypoplasia, whereas prenatal decompression at day 120 was associated with normal neonatal respiratory function.[6] However, variable success rates of pleuroamniotic shunting in bilateral hydrothorax in the human fetus have been reported.[3-5] Often the study described was not limited to isolated pleural effusions but also included fetuses with associated hydrops and/or other structural anomalies. Moreover, data on the natural history of isolated bilateral fetal hydrothorax are lacking.

We report the outcome of eight such fetuses with isolated bilateral pleural effusions in whom a conservative approach was adopted.

Material and methods

Between August 1986 and August 1988, 1890 pregnant women were referred for a fetal anomaly scan because of an abnormal ultrasound finding elsewhere. In 278 cases a fetal structural anomaly was diagnosed, eight of which were documented as isolated bilateral hydrothorax. In all eight cases the reason for referral was polyhydramnios. Maternal age ranged between 22 and 32 years (median, 28 years), maternal parity varied between 1 and 4 (median, 2), and gestational age ranged between 25 and 39 weeks (median, 33 weeks). The ultrasound equipment used was a Diasonics Cardio Vue 100 mechanical sector scanner with a 3.5 or 5.0 MHz transducer. Fluid in the fetal pleural cavity produces a sonolucent image with the lateral and inferior borders shaped by the thoracic wall and diaphragm. The fetal lung appears in the shape of a butterfly wing as an echo-dense area.[7] A diagnosis of isolated bilateral fetal hydrothorax was made if pleural effusions were present in the absence of hydropic changes and other structural malformations. In this series of cases polyhydramnios was defined as a large fluid pocket of 8 cm or more.[8]

When isolated fetal hydrothorax is present, chylothorax and intrauterine infections must be considered.[9] After the initial diagnosis, maternal blood samples were examined for cytomegalovirus, *Toxoplasma gondii*, and rubella infections. Serial ultrasound scans were performed at 2-week intervals to (1) measure the degree of pleural effusion and (2) monitor fetal growth by means of measurement of the upper abdominal cir-

cumference,[10] and fetal well-being according to the biophysical profile score.[11]

Data on fetal and neonatal outcome were obtained in all eight cases of isolated bilateral fetal hydrothorax.

Results

A diagnosis of isolated bilateral fetal hydrothorax and polyhydramnios was confirmed in all eight cases. Maternal blood samples showed no evidence of recent infections.

Serial ultrasound scans revealed spontaneous resolution of pleural effusion in two cases (at 33 and 37 weeks), whereas in the remaining six, no remarkable change in the degree of bilateral hydrothorax was observed. Fetal growth was normal, and the biophysical profile demonstrated that except for polyhydramnios, there was no sign of fetal compromise. All eight pregnancies resulted in the delivery of a live infant (two males and six females). Two infants were delivered at 33 and 36 weeks, respectively. The remaining six infants were born between 38 and 41 weeks of gestation, four spontaneously and two by cesarean section, because of breech presentation or cervical dystocia. Fetal birth weights were situated between the tenth and ninetieth percentiles according to the tables of Kloosterman[12] and were corrected for maternal parity and fetal sex. No congenital anomalies were present. Apgar score at five minutes was 8 or more in seven of eight cases and six in the remaining case. Neonatal development was uneventful in the two infants with spontaneous resolution of pleural effusion. All six infants with isolated bilateral hydrothorax at birth were intubated as a preventive measure immediately after delivery. This was always followed by spontaneous respiration, reflecting lung expansion. After confirmation of isolated bilateral hydrothorax by ultrasonography or chest x-ray films, thoracocentesis was performed under sedation by means of silicone rubber diversion catheters under ultrasonic guidance. The amount of serous fluid collected varied between 50 and 500 ml. In four of six infants, intubation was only maintained for about 30 minutes because of normal lung expansion.

In two infants intubation was sustained for 7 days because of signs of developing respiratory distress as a result of prematurity in one and recurrent fluid accumulation in the pleural cavity necessitating drainage over a 5-day period in the other infant. Chylothorax was established in two cases (one male and one female), including the infant with long-term ventilation support and pleural drainage. A diagnosis of chylothorax was made in the presence of 20 to 50 leukocytes per high-power field, with 90% or more consisting of lymphocytes, and fluid and protein content approaching that of plasma.[13] In the remaining four infants, no signs of chylothorax could be documented. All eight infants were alive and well at the age of 1 month.

Comment

When fluid is found in the fetal chest, a number of other fetal problems must be considered. These include fetal hydrops, whether caused by erythroblastosis or nonimmunologic causes, as well as intrauterine infections.[9] The present study only deals with isolated bilateral fetal hydrothorax. Chylothorax was present in two cases, whereas in the remaining six no cause for pleural effusion could be established. Polyhydramnios was documented in all cases. It has been hypothesized that the onset of polyhydramnios may represent decompensation of amniotic fluid homeostasis caused by collapse of the fetal lung.[9] This is not supported by our observations of normal lung development after birth. Another explanation may be interference with normal swallowing due to increased intrathoracic pressure.[9] Although a few reports on successful prenatal chest drainage have appeared,[2, 3, 5] it should be realized that there is a risk of fetal and maternal harm, such as bleeding after puncture of fetal or maternal vessels, fetal organ damage, premature rupture of the membranes, and premature labor. Moreover, pleuroamniotic shunting may result in technical failure as a result of shunt instability, with the latter risk greatly reduced during the neonatal period. Our conservative approach to isolated bilateral fetal hydrothorax has led to two important observations: (1) that isolated bilateral hydrothorax may resolve spontaneously during fetal life and (2) that fetal outcome may be good without prenatal invasive procedures. The essence of a prenatal diagnosis of isolated bilateral fetal hydrothorax seems to be determined more by the possibility of forewarning the neonatologist, thereby allowing effective diagnostic and therapeutic measures to be taken as soon as delivery has occurred.

To determine the efficacy of prenatal thoracocentesis and pleuroamniotic shunts, several issues must be addressed. First, no large study is available on the natural history of isolated bilateral fetal hydrothorax, although in one report,[14] the mortality rate of chylothorax has been estimated at 5%. Second, better criteria for selecting the fetus with normal pulmonary development should be developed. Third, if an infant survives after successful prenatal chest drainage, it does not necessarily follow that the procedure was beneficial.

Although we do not suggest that conservative management of isolated bilateral fetal hydrothorax will always result in a successful fetal outcome, our results seem to justify a larger study on the natural history of this particular disorder. Because of the risks attached to any invasive intrauterine procedure, a prospective randomized trial should be carried out to compare sur-

vival with and without prenatal shunting in the fetus with isolated bilateral fetal hydrothorax. Since the prevalence of this disorder is very low, the answer can only be obtained through a multicenter study.

Relapsing polychondritis in pregnancy: A case report and review

Martin L. Gimovsky, MD, and Mark Nishiyama, MD
Los Angeles, California

A case of relapsing polychondritis is reported. This woman was delivered of two normal infants at term.
(AM J OBSTET GYNECOL 1989;161:332-4.)

Key words: Chronic pulmonary disease, pregnancy

Relapsing polychondritis is an uncommon inflammatory disease, characterized by secondary degenerative changes in cartilaginous tissue. Symptoms are diverse, and pathologic changes in cartilage may result in serious pulmonary and cardiovascular sequelae. In 1956 a case was reported of an infant born to a woman with relapsing polychondritis who manifested symptoms identical to those of the mother, suggesting a humorally mediated process. A case is presented here in which a woman diagnosed as having severe relapsing polychondritis was delivered of two normal term infants.

Case report

A 26-year-old woman, gravida 2, para 1, was first seen by the Obstetrical Service at the White Memorial Medical Center at an estimated gestational age of 17 weeks. Her past medical history was significant for episodic shortness of breath with increasing wheezing over the past 7 years. She was initially diagnosed as "asthmatic" and treated with bronchodilators with little improvement in her symptoms. Two years afterward, she underwent a successful term pregnancy with the delivery of a normal female infant, 7 pounds 10 ounces, with subsequent normal neonatal course. In the 4 years that followed, her condition steadily worsened and she was first seen at White Memorial Medical Center 2 years before her second pregnancy for acute exacerbation of

"chronic asthma." At that time ear and nose abnormalities were noted, including saddle nose deformity and auricular chondritis. Consultation with an ear, nose, and throat specialist was obtained. Further history confirmed a 1-year history of pain and swelling in both helices. Neurosensory hearing loss was present but minimal. The suspected diagnosis of relapsing polychondritis was confirmed by biopsy (of auricular cartilage). The biopsy specimen contained an infiltrate of lymphocytes and plasma cells at the cartilage–connective tissue interface. Chest x-ray film revealed marked stenosis of the left mainstem bronchus and tracheal narrowing from the level of T4 to the carina. The patient required intubation and high-dose corticosteroids through several successive hospitalizations and thereafter was managed on a regimen of varying doses of prednisone and dapsone.

At the beginning of her second pregnancy physical examination revealed a cushingoid white female with bilateral auricular chondritis and a saddle nose deformity. Inspiratory and expiratory wheezes were evident. There was no evidence of ocular involvement. A grade II/VI systolic ejection murmur was present. Uterine size was small for dates and an initial ultrasonography was performed. Arterial blood gas measurements while she was breathing room air showed a P_{O_2} of 77 mm Hg, P_{CO2} of 44 mm Hg, and pH of 732. Medications included prednisone USP 5 mg daily, lorazepam 0.5 mg twice a day, and dapsone USP 50 mg daily.

Pulmonary function testing revealed a forced expiratory volume at 1 second of 1.1 L (43% of predicted value). The forced expiratory volume at 1 second/forced vital capacity was 71% of the predicted value. Maximum voluntary ventilation was 32 L/min, 30% of the predicted value. Test results for antinuclear antibody and rheumatoid factor were negative. A 24-hour total urine collection was within normal limits. An echocardiogram was normal.

Fetal growth was evaluated by serial ultrasonography. At 17 weeks the patient complained of increasing shortness of breath with productive cough. History revealed the patient had taken herself off prednisone. She was restarted on a regimen of prednisone, 5 mg daily, and was given a course of ampicillin. At 23 weeks of gestation, increased wheezing was noted and a blood gas analysis while she was breathing room air revealed a P_{O_2} of 74 mm Hg, P_{CO_2} of 26 mm Hg, and pH of 747. The patient was treated with an inhalational bronchodilator and was noted to be much improved 3 days later. At 26 weeks prednisone was increased to 10 mg daily and dapsone was discontinued. A repeat diabetic screen was within normal limits. A productive cough recurred at 36 weeks and was again treated successfully with ampicillin. At 40½ weeks' gestation the patient underwent an uneventful labor and spontaneous delivery. She was given additional hydrocortisone peripartum (100 mg hydrocortisone every 8 hours for three doses). She was delivered of a 3189 gm male infant with Apgar scores of 7 and 9.

Evaluation of the infant failed to disclose any abnormalities. Follow-up of the infant at age 1 and 2 years demonstrated a normal course.

Table I. Clinical and histopathologic features of relapsing polychondritis[1]

Clinical
1. Recurrent chondritis of the auricles
2. Inflammation of ocular structures, including conjunctivitis, keratitis, scleritis, and/or uveitis
3. Chondritis of laryngeal and/or tracheal cartilage
4. Cochlear and/or vestibular damage manifest by neurosensory hearing loss, tinnitus, and/or vertigo
5. Seronegative inflammatory polyarthritis
Histopathologic
1. Loss of basophilic staining of cartilage matrix
2. Perichondral inflammation
3. Cartilage destruction and replacement with fibrous tissue
4. Cellular damage to chondrocyte

Comment

Episodic dyspnea coupled with inspiratory and expiratory wheezing in a woman of child-bearing age immediately suggests the diagnosis of reversible bronchoconstriction ("asthma"). The inability to obtain a satisfactory response to bronchodilators suggests other forms of obstructive pulmonary disorders seen in the child-bearing years such as cystic fibrosis and α_1-antitrypsin deficiency. Both of these disorders include a significant fetal risk in addition to the potential for serious maternal sequelae.

Relapsing polychondritis is a multisystem disorder characterized by the potential for destruction of cartilage with fibrous tissue replacement. The diagnosis is based on a combination of clinical criteria with pathologic confirmation (Table I). These criteria are both clinical and histopathologic. When three or more of these criteria are met, including biopsy confirmation, the diagnosis may be considered "certain."[1]

Involvement of the respiratory tract is reported as the cause of most of the deaths in relapsing polychondritis. The patient manifests dyspnea, wheezing, cough, a choking sensation, and tenderness over the thyroid cartilage or anterior cervical trachea. Airway obstruction and pulmonary infection are common.

The arthritis of relapsing polychondritis may involve large or small joints. Initially the symptoms may be migratory and resemble rheumatoid arthritis.

Cardiovascular manifestations occur in approximately 25% of patients with relapsing polychondritis. Dilatation of the ascending aorta with destruction of the aortic valve cusps may result in aortic regurgitation or aortic aneurysm.

Renal involvement is less common. Biopsy specimens show glomerulonephritis with immunoglobulin G, immunoglobulin M, and C 3 deposits consistent with an immune complex etiology.

Laboratory findings are inconsistent. More than half of the patients have anemia resulting from chronic disease and an elevated sedimentation rate. A minority will have an increase in quantitative immunoglobins, a positive rheumatoid factor, and a false-positive serologic test result.

An autoimmune pathogenesis is suggested by the presence of circulating antibodies to type II collagen in patients with relapsing polychondritis. These antibodies appear to correlate with the clinical severity of symptoms. Cellular mediated immunity has been demonstrated by lymphocyte transformation in response to proteoglycans in relapsing polychondritis. In a rodent model in which autoimmunity to type II collagen is induced, inflammatory ear lesions and acute arthritis have been produced.[2] The pathologic changes include loss of basophilic staining of cartilage matrix, inflammatory cell infiltration, phagocytosis of chondrocytes, and total destruction of cartilage with fibrous replacement. In the case report[3] of an infant born to a woman with relapsing polychondritis who manifested symptoms at birth, the infant's symptoms, which included anemia of uncertain cause and transient arthritis, cleared in the first year of life, which is consistent with a transplacental humorally mediated process.

Treatment has been primarily symptomatic, with both corticosteroids and nonsteroidal antiinflammatory drugs used during active episodes. Dapsone has been used extensively because of its ability to inhibit lyzosomal enzymes in hypervitaminosis A–induced chondritis, a condition histologically similar to relapsing polychondritis. Because of its folic acid antagonism, in addition to the risk of Stevens-Johnson syndrome and neutropenia, use of dapsone is a significant risk during pregnancy.

Relapsing polychondritis may be an example of a humorally mediated autoimmune disease that may affect both the fetus and newborn by transplacental antibody passage. Chronic respiratory insufficiency in a gravid woman that is not responsive to standard therapy should always be further investigated for less likely causes, which include systemic disorders such as relapsing polychondritis.

Abscess of allantoic duct remnant

I. Cori Baill, MD, G. William Moore, MD, PhD, and Lora A. Hedrick, MD
Baltimore, Maryland

A recently submitted placenta was found to be histopathologically unique. Funicitis was present at the early gestational age of 22 1/7 weeks, and an abscessed allantoic duct remnant was present. The latter finding had not previously been seen at this pathology department, nor could reference to it be found in the literature. (Am J Obstet Gynecol 1989;161:334-6.)

Key words: Allantoic duct remnant, funicitis, placenta pathology

A 17-year-old para 0-0-1-0 woman registered for prenatal care at dates equal to examination at 8 4/7 weeks' gestation. Her registration cervical culture was positive for gonococcus. Subsequent to treatment with oral ampicillin 3.5 gm and oral probenecid 1.0 gm, her culture was negative. She also was prophylactically treated for *Chlamydia* with standard doses of erythromycin. Ampicillin was prescribed 5 days before her admission, secondary to a positive cervical culture for group B streptococci.

The patient was admitted with a 21-hour history of

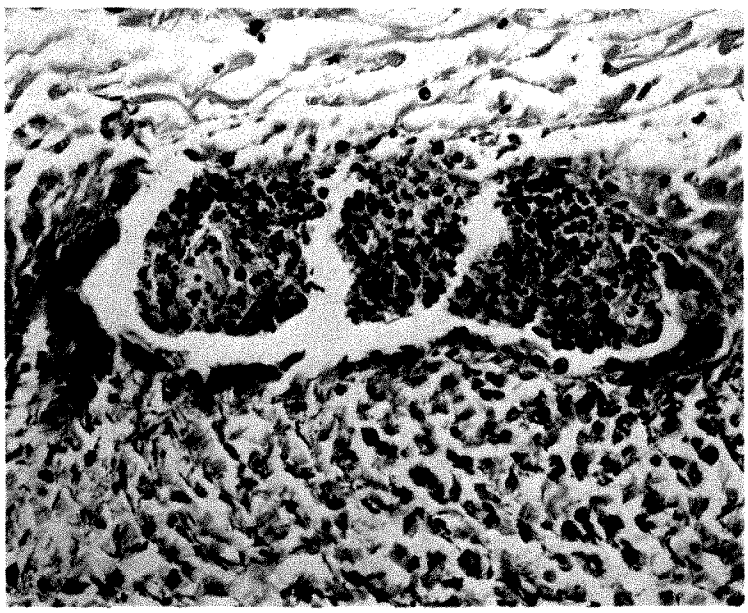

Fig. 1. Abscess of allantoic duct remnant. Typical type of transitional epithelial lining of allantoic duct remnant enclosed pool of polymorphonuclear leukocytes. (Hematoxylin and eosin stain; original magnification ×400.)

cramps, lower abdominal pain, and back pain. Her initial physical examination revealed the following: temperature, 37.7° C; fetal heart rate, 160 to 170 beats/minute; maternal heart rate, 102 beats/minute; respirations, 18; blood pressure, 110/67; fundal height, 21 to 22 cm; cervix, 3 to 4 cm; 50% effaced; fern negative. The best obstetric estimate at admission was 22 1/7 weeks' gestation, established by her early examination that was consistent with the last menstrual period, and an ultrasonographically derived gestational age of 19.9 weeks at dates of 19 weeks. Ritodrine tocolysis failed, and 7 hours after her admission the patient was delivered of a 540 gm girl with Apgar scores of 1 at 1 minute and 1 at 5 minutes.

Findings

The placenta weighed 210 gm and was grossly normal for gestational age. Histopathologic evidence of chorioamnionitis and funicitis with allantoic duct abscess were present. The chorioamnionic membrane showed massive infiltration with polymorphonuclear leukocytes and gram-negative bacterial overgrowth that extended from the decidua into the amnionic membrane. The amnionic epithelium was intact, but the chorionic cells were largely necrotic.

The umbilical vein showed marked infiltration by polymorphonuclear leukocytes that extended beyond the muscular wall and into the Wharton's jelly. The two umbilical arteries had leukocytes within, but not beyond, the muscular wall. The allantoic duct remnant showed a small abscess that consisted of leukocytes with a fragmented transitional lining (Fig. 1). There was mild condensation of Wharton's jelly around the duct remnant.

Comment

Funicitis in this case presumably resulted from margination and subsequent migration of fetal leukocytes into the media around the umbilical vessels. The sequence of cord inflammatory lesions tends to be a progression from vein involvement, to the arteries, and finally to the cord substance.[1] Allantoic duct remnant involvement in this case may have resulted from contiguous spread.

Lavery[1] states that inflammatory lesions of the cord are quite unusual at less than 26 weeks' gestation, and this observation is supported by Chellam and Rushton's[2] study of chorioamnionitis and funicitis in the placentas of 200 neonates that weighed <2500 gm. They found inflammatory lesions present in 48.5% of all specimens, but only 9.5% involved the cord. Allantoic duct remnants were not noted to be involved.

During the third to fifth weeks' gestation the allantois is responsible for fetal blood formation. Its blood vessels comprise the umbilical vessels of the forming umbilical cord. At 3 to 4 weeks' gestation, cephalocaudal flexion of the embryo leads to fusion of the yolk sac projection and its vitelline vessels to the connecting stalk that continues the allantois and umbilical vessels, and thus forms the cord at 5 to 6 weeks' gestation.[2]

Sections taken from just beyond the fetal end of the cord, but rarely at the maternal end, commonly reveal

allantoic duct remnants.[1] The allantoic duct remnant is usually situated between the two umbilical arteries and is generally lined by flattened transitional epithelium. The duct wall may have condensation of Wharton's jelly. In contrast, yolk sac (omphalomesenteric duct) remnants are situated at the margin of the cord, are usually cubical or columnar epithelium, and may contain mucus. These rarely differentiate toward gastrointestinal-type structures. Cysts, polyps, a duct lined by gastric-type mucosa, and nodules that contain pancreatic or small bowel tissue have been described.

In summary, this is a case of an abscess in an allantoic duct remnant, secondary to the presence of funicitis in a 22 1/7 weeks' gestation umbilical cord.

Infection and labor

IV. Cachectin–tumor necrosis factor in the amniotic fluid of women with intraamniotic infection and preterm labor

Roberto Romero, MD, Kirk R. Manogue, PhD, Murray D. Mitchell, DPhil, Ying King Wu, MD, Enrique Oyarzun, MD, John C. Hobbins, MD, and Anthony Cerami, PhD

New Haven, Connecticut, New York, New York, and Salt Lake City, Utah

A growing body of evidence supports a causal link between subclinical intrauterine infection and preterm labor. The mechanisms responsible for the onset of parturition in this setting have not been elucidated. The conventional view has been that bacterial products increase prostaglandin biosynthesis by intrauterine tissues and this, in turn, leads to the onset of labor. An alternative or complementary mechanism is that microbial products activate the host monocyte-macrophage system and that cytokines released during this process signal the initiation of parturition by stimulating prostaglandin biosynthesis by intrauterine tissues. This study was conducted to determine if cachectin–tumor necrosis factor is present in the amniotic fluid of women with intraamniotic infection and whether this cytokine can alter the rate of prostaglandin biosynthesis by intrauterine tissues. Amniotic fluid from 54 women was assayed for tumor necrosis factor. Tumor necrosis factor was not detectable in the amniotic fluid of women without intraamniotic infection regardless of the presence or absence of term or preterm labor. On the other hand, the amniotic fluid of 11 of 15 women with preterm labor and intraamniotic infection had measurable tumor necrosis factor. This cytokine stimulated prostaglandin E_2 biosynthesis by amnion cells in monolayer culture in a dose-dependent fashion. These data support the concept that macrophage activation is involved in the onset of human parturition in the setting of infection. We propose that the host (fetus and/or mother) signals the onset of parturition through the secretion of inflammatory cytokines released in response to bacterial invasion. (Am J Obstet Gynecol 1989;161:336-41.)

Prematurity is the leading cause of perinatal mortality and morbidity worldwide.[1] Accumulating evidence indicates that preterm labor is causally related to subclinical intrauterine infection.[2] Increased biosynthesis of prostaglandins by intrauterine tissues is widely accepted as a key event in the initiation of parturition.[3] Mechanisms responsible for increased bioavailability of prostaglandins in preterm labor associated with infection have not been defined. The conventional view has been that bacteria and their products are responsible

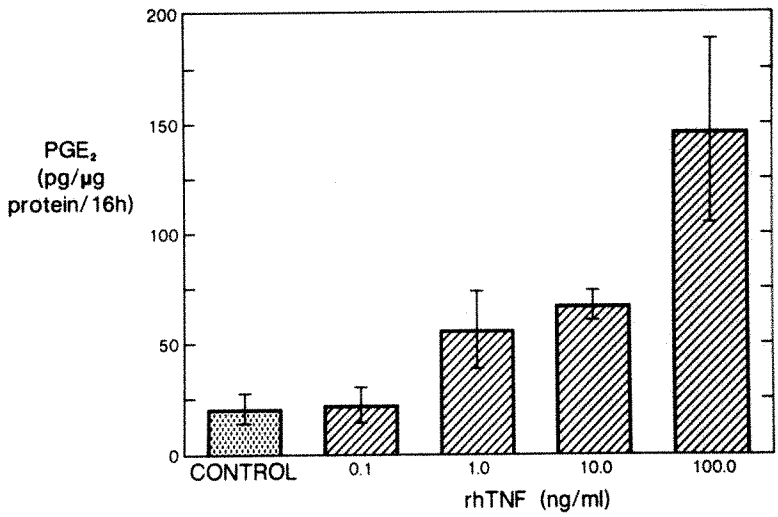

Fig. 1. Effect of different concentrations of rHuTNF on prostaglandin production by amnion cells in primary culture (representative experiment). Mean and SEM are depicted.

for the increased biosynthesis of prostaglandins that results in the onset of labor.[4,5] However, in recent years, it has been recognized that many of the metabolic derangements associated with microbial infection are mediated by endogenous factors.[6] Cachectin–tumor necrosis factor (TNF), a monokine produced in response to bacterial lipopolysaccharide, is an inflammatory mediator implicated in the pathogenesis of shock and cachexia associated with infection.[6] TNF stimulates prostaglandin production by several cell types.[7] Thus we hypothesize that bacterial products stimulate fetal and/or maternal cells to produce a network of interacting cytokines (including interleukin-1 and TNF), which in turn increase prostaglandin biosynthesis by intrauterine tissues and results in the onset of labor. To test this hypothesis, the concentration of TNF was measured in amniotic fluid of women in preterm labor, and the effect of this monokine on prostaglandin biosynthesis by human amnion was determined.

Material and methods

Study design. Amniotic fluid was collected from 54 women classified into four groups: group 1, women with term pregnancies without labor or infection (n = 14); group 2, women with term pregnancies in active labor (cervical dilatation >6 cm) but without infection (n = 13); group 3, women with preterm labor leading to preterm delivery within 24 hours of admission but without infection (n = 12); group 4, women with preterm labor and intraamniotic infection (n = 15). An intraamniotic infection was defined as the presence of a positive amniotic fluid culture whether or not clinical signs of chorioamnionitis were present. Labor was defined as the presence of regular uterine contractions that led to cervical dilatation and spontaneous vaginal delivery. Amniotic fluid was obtained by transabdominal amniocentesis from all women except for those in group 2. In our institution, amniocentesis is performed routinely on all women with preterm labor and/or premature rupture of membranes to screen for intraamniotic infection. Patients in group 1 had amniocentesis for evaluation of lung maturity before an elective cesarean section. Patients in group 2 had a transvaginal amniotomy when they were in active labor at >6 cm of dilatation. No serial samples from the same patient were included in this study.

Amniotic fluid culture technique. Amniotic fluid was transported to the laboratory in a capped plastic syringe immediately after amniocentesis. Amniotic fluid was plated within 30 minutes of collection in all cases. Cultures for aerobic and anaerobic bacteria, *Mycoplasma hominis* and *Ureaplasma urealyticum* were performed. Methods of bacterial culture and identification have been described previously in detail.[8] *Mycoplasma* species were cultured with a commercially available system (Mycotrim-GU, Berkeley, Calif.).

Quantitation of TNF. The cachectin-TNF concentration in amniotic fluid was measured by modification of the standard L-929 cell cytotoxicity assay in the presence of actinomycin D.[9] Aliquots of amniotic fluid were thawed and diluted 1 : 10 in Dulbecco's modified Eagle's medium supplemented with 10% fetal bovine serum and filter sterilized. Aliquots of 50 μl were then added in triplicate to microtiter plate wells already containing subconfluent (1×10^5) L-929 cells under 50 μl fresh Dulbecco's modified Eagle's medium–fetal bovine serum with actinomycin D (2 μg/ml) and with or without TNF-neutralizing monoclonal antibody (MAb 2-2-3E3, a gift from Chiron Corp., Emeryville, Calif.) at a final antibody concentration of 10 μg/ml. This concentration of anti-TNF antibody is sufficient to neutralize more than 5 ng of recombinant human cachectin–TNF

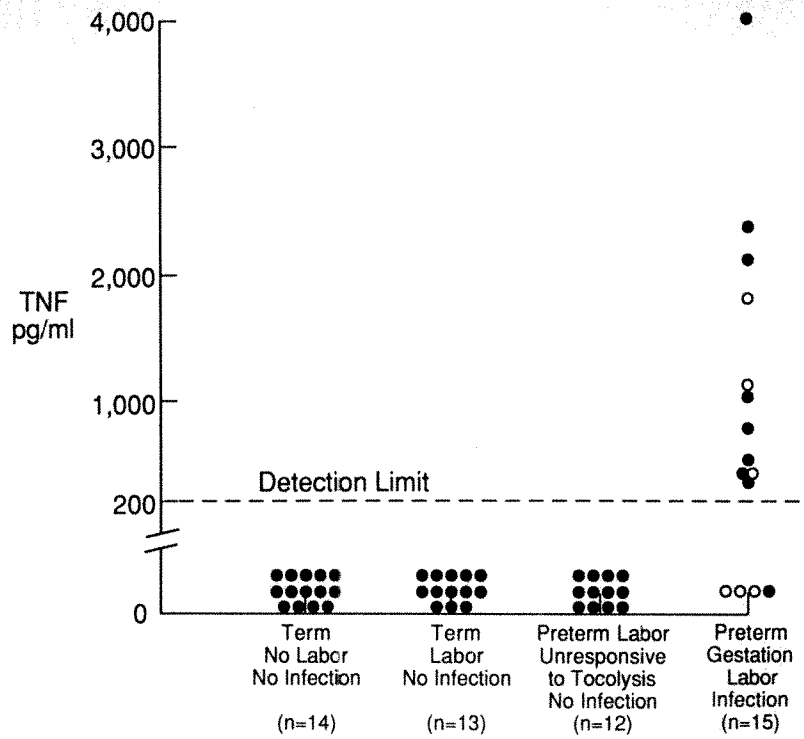

Fig. 2. Amniotic fluid concentrations of TNF in different study groups. *Open circles* represent women with premature rupture of membranes. *Solid circles* represent women with preterm labor and intact membranes.

[(rHuTNF), also donated by Chiron Corp.] per well (500 units). A series of triplicate standards was included on each assay plate. Final concentrations were no TNF; 41 ng rHuTNF/ml; and 4.1 ng/ml to 8 pg/ml in a ×2 dilution series. After an 18-hour incubation at 37° C in a humidified 5% carbon dioxide incubator, viable cells were estimated by their ability to reduce thiazolyl blue (MTT; Sigma Chemical Co., St. Louis) to a colored formazan[10, 11] during an additional 4-hour incubation after the addition of 10 μl MTT (5 mg/ml) to each well. Wells were then aspirated dry and cells lysed with 100 μl of 0.04N hydrochloric acid in isopropanol and metabolized dye further solubilized with 100 μl water. Optical densities were read in a dual wavelength 96-well microtiter plate reader (Bio-Tek Instruments, Burlington) at 570 and 690 nm. Mean sample (or standard) optical densities were converted to percent cells dead using the mean optical density of control (no rHuTNF added) wells as 0% cells dead and the mean optical density of 41 ng rHuTNF/ml wells as 100% cells dead for each assay plate. Percent cells dead is linearly related to the log concentration of rHuTNF with good agreement over the range 10% to 90% cells dead (data not shown). For each sample (in both presence and absence of a neutralizing antibody), an equivalent concentration of rHuTNF was interpolated from the mean rHuTNF dilution curve of cytotoxicity. These interpolated values were multiplied by 20 to account for dilution of the original samples. The difference (equivalent picograms per milliliter without antibody minus equivalent picograms per milliliter with antibody) was used to represent TNF-specific cytotoxicity. In general, 10% cells dead corresponds to approximately 10 pg rHuTNF per milliliter assay medium. Thus the lower limit of detection is approximately 200 equivalent pg rHuTNF per milliliter of undiluted amniotic fluid. At 1:20 final dilution, only three of 54 samples had >10% cytotoxicity that was not neutralized by the anti-TNF antibody. These samples were considered negative for TNF. Cytotoxicity in all other samples was reduced to <10% in the presence of the TNF-neutralizing antibody.

Prostaglandin production by human amnion. Experiments to evaluate the effect of TNF on prostaglandin biosynthesis by intrauterine tissues were conducted on human amnion in primary culture. This system has been shown to be morphologically, enzymatically, and biochemically similar to fresh amnion.[12] Amnion was taken from patients having elective cesarean section at term, before the onset of labor. Amnion cultures were established as previously described.[12] Purified rHuTNF (>98% pure by sodium dodecyl sulfate–polyacrylamide gel electrophoresis, 1×10^8 U/mg, 25 ng of endotoxin per milligram of protein by *Limulus* amebocyte lysate test; Chiron Corp.) was added to amnion cells with final concentrations of 0.1, 1, 10, and 100 ng/ml in Dulbecco's modified Eagle's medium.

Table I. Clinical, microbiologic, and amniotic fluid TNF data in women with preterm labor and intraamniotic infection

Patient identification no.	*Gestational age (wk)*	*Organism*	*Colony count (cfu/ml)*	*Amniotic fluid TNF (pg/ml)*	*Membrane status*

Incubations were conducted for 16 hours at 37° C in a humidified incubator. Each condition of testing was repeated in a given primary amnion culture in replicates of four. The effect of rHuTNF on amnion production of prostaglandin E_2 (PGE_2) was examined in primary cultures from five separate patients. PGE_2 is the main product of arachidonic acid metabolism in amnion. PGE_2 was measured by a specific and sensitive radioimmunoassay previously described in detail.[13] Protein quantification was performed by the method of Lowry et al.

Statistical analysis. The effect of TNF on PGE_2 biosynthesis by amnion cells was examined by analysis of variance with a factorial design. A logarithmic transformation of PGE_2 output by amnion cells data was performed before analysis.

Results

Fig. 1 illustrates a representative experiment of the effect of TNF on the production of PGE_2 by human amnion. A concentration-dependent stimulation was observed in all of the five amnion cell cultures A significant increase in PGE_2 biosynthesis occurred at TNF final concentrations of 1, 10, and 100 ng/ml ($p < 0.001$). A significant variability existed in the basal rate and in the maximum rate of PGE_2 production in response to TNF among different amnion cell cultures ($p = 0.0001$).

Fig. 2 displays the concentrations of TNF in amniotic fluid of women in the four study groups. No detectable TNF was found in the amniotic fluid of women at term with or without labor (groups 1 and 2). Similarly, TNF was not detected in the amniotic fluid of women with preterm labor and without intraamniotic infection (group 3). Of 15 patients with intraamniotic infection and preterm labor, 11 had detectable TNF. Table I displays the microbiologic features and TNF concentrations in each patient with intraamniotic infection (group 4).

Comment

The mechanisms responsible for the onset of labor in patients with intraamniotic infection are poorly understood. A role for prostaglandins is suggested by their increased concentration in amniotic fluid in women with intraamniotic infection.[14] The signals responsible for their increased bioavailability in this setting have not been elucidated. To date, research has focused on the role of bacteria on arachidonic acid metabolism by human amnion. Microorganisms indigenous to the genital tract have been shown to have phospholipase activity,[4] and microbial products can stimulate the production of prostaglandin E by amnion cells in culture.[5]

We have also demonstrated that endotoxin stimulates prostaglandin production by intrauterine tissues (amnion and decidua) in a dose-dependent manner.[15] However, the concentrations of endotoxin required to elicit a significant stimulation in prostaglandin biosynthesis in vitro is often higher than that found in patients with intraamniotic infection. This suggests that a direct endotoxin effect may not be the sole mechanism by which microorganisms lead to the onset of human parturition. It is possible that microbial products other than endotoxin may play a role.

An alternative hypothesis is that the signals for the onset of human parturition are of host origin. Bacterial endotoxin can induce TNF production by a host cell(s)

that in turn stimulates prostaglandin production by intrauterine tissues. Our data clearly show that TNF stimulates PGE_2 biosynthesis by human amnion over a range of TNF concentrations detected in amniotic fluid of women with intraamniotic infection and preterm labor. These observations are consistent with the effects of TNF on arachidonic acid metabolism reported in other cell types.[7] The stimulatory effect of rHuTNF on the biosynthesis of PGE_2 by amnion cells cannot be attributed to contamination of the recombinant material with endotoxin because nanogram quantities of this bacterial product are generally required to stimulate PGE_2 biosynthesis by human amnion.[16] Our data suggest that amniotic fluid TNF does not play a role in the onset of physiologic labor at term or in preterm labor not associated with intraamniotic infection because TNF could not be detected in amniotic fluid from women with these clinical conditions (groups 2 and 3). TNF was present in women with intraamniotic infections and preterm labor (group 4). This suggests that a host-mediated response, evidenced by TNF concentrations, is associated with the onset of parturition in this particular subset of patients.

Although amniotic fluid TNF concentrations have been measured as an index of host response to microbial infection, this is not the only host product capable of stimulating prostaglandin biosynthesis by human intrauterine tissues. Interleukin-1[17] and platelet activating factor (PAF) have been identified in the amniotic fluid of women with intraamniotic infection (Hoffman D, Romero R, Johnston J, unpublished observations) and can also increase prostaglandin biosynthesis by human amnion[18] and decidua (unpublished observations). Thus TNF may be only one of several mediators utilized by the host to signal the initiation of labor. Interleukin-1 or PAF may be involved synergistically or predominantly in the cases of preterm labor with intraamniotic infections in which amniotic TNF either is not detectable or is not in the range required for significant stimulation of prostaglandin production. Indeed, synergism between interleukin-1 and TNF in the stimulation of prostaglandin production by synovia has been demonstrated. TNF produced by human decidua may play a role in the initiation of labor in cases of extraamniotic infection (deciduitis). Macrophages in decidua produce TNF in response to bacterial products and this cytokine stimulates prostaglandin production by decidual cells.[19] The relative importance of the different components of the cytokine network in human parturition has not been established. We have recently determined that interleukin-1 is more potent than TNF and endotoxin in stimulating prostglandin biosynthesis by intrauterine tissues (unpublished observations). Furthermore, interleukin-1 is present more frequently than TNF in the amniotic fluid of women with intraamniotic infection and preterm labor. Therefore it is tempting to conclude that interleukin-1 may participate to a greater extent than TNF in this process.

On the basis of these data, we propose a model in which the initiation of human parturition in the presence of infection is controlled by the host. Systemic maternal infections such as pyelonephritis or localized infections such as deciduitis could trigger parturition by activating the maternal monocyte-macrophage system. A second host, the fetus, may also signal the onset of labor when the infection has extended to the intraamniotic cavity and activates the fetal immune system. Preterm labor can therefore be viewed as an event occurring when the intrauterine or maternal environment is hostile and threatens the well-being of the fetus and/or mother.

Pulsed Doppler flow-velocity waveforms in the prediction of fetal hematocrit of the severely isoimmunized pregnancy

Joshua A. Copel, MD, Peter A. Grannum, MD, Jacqueline J. Green, MS, RDMS, Kathy Belanger, PhD, and John C. Hobbins, MD

New Haven, Connecticut

We previously reported a significant relationship between the hematocrit levels of anemic fetuses and information derived from ultrasonographic and Doppler flow-velocity waveforms. In this study we prospectively tested two formulas for the prediction of hematocrit values, by use of gestational age, presence or absence of hydrops, and Doppler indices. Although one of the two formulas predicted hematocrit values significantly, the only component of the formula that made a significant contribution was fetal hydrops. We conclude that currently available fetal Doppler measurements are unable to be applied in the prospective prediction of hematocrit values in anemic fetuses of isoimmunized pregnancies. (Am J Obstet Gynecol 1989;161:341-4.)

Key words: Prenatal diagnosis, ultrasonography, Doppler ultrasonography, fetal treatment, erythroblastosis fetalis, isoimmunization

Management of the severely isoimmunized pregnancy has recently evolved from indirect to direct means of fetal evaluation and treatment. Amniotic fluid optical density measurements of bilirubin may now be supplemented with fetal phlebotomy and direct hematocrit determinations, and intraperitoneal transfusion is rapidly being replaced by fetal intravascular transfusion.

A continuing question in the management of such patients has been the proper place of fetal blood sampling. Although valuable information may be gained, the procedure presently carries a higher inherent risk than amniocentesis and can be performed with limited frequency. A noninvasive means of determining the fetal hematocrit would obviously be preferable in the evaluation of patients, before the initiation of a course of transfusions and to determine the optimal timing of follow-up transfusions.

The use of fetal Doppler flow velocity waveforms has been proposed as an indirect means of gaining information concerning the fetal hematocrit. Based on the reports of other investigators,[1-3] we previously reported that equations could be derived that relate Doppler waveforms to fetal hematocrit.[4] We now report a prospective trial of the ability of Doppler information to predict hematocrit.

Material and methods

Between August 1, 1987, and March 1, 1988, 13 patients were referred to the Yale Perinatal Unit because of severe isoimmunization for intravascular transfusion therapy. Gestational ages varied from 20 to 32 weeks (mean, 27 weeks). All patients had evidence of erythroblastosis on the basis of indirect Coombs tests and either fetal hydrops or amniotic fluid optical density measurement in zone III or upper zone II by Liley curves.

Before initial intravascular transfusion in all patients had full ultrasonographic evaluation of gestational age

*Hydropic fetuses.

and gross anatomy, including fetal echocardiography. Fetal weight was estimated according to Shepard et al.,[5] except in cases of gross fetal hydrops, when a mean weight for estimated age was used since abdominal distention would invalidate the Shepard formula. Four of the fetuses in this report were hydropic at the time of study.

Pulsed Doppler waveforms were obtained from the fetal umbilical artery and descending aorta during periods of fetal apnea (General Electric model RT 3600, GE, Milwaukee). Three consecutive umbilical waveforms were analyzed by means of the Pourcelot index, systolic/diastolic ratio, and pulsatility index[2] and the mean value was calculated. The fetal descending aortic signal was angle corrected at the time it was obtained. Both pulsatility index and peak aortic velocity were calculated, with the mean of three values used.

Fetal transfusions were performed as previously described.[6, 7] Before blood infusion, sufficient fetal blood was removed for measurement of hemoglobin and hematocrit values by standard automated technique. Fetal origin of the blood was confirmed by Kleihauer-Betke staining.

Doppler results were stored on a spreadsheet in a personal computer and previously reported formulas relating Doppler information to fetal hematocrit were calculated.[4] The two formulas used were:

$$\text{Hematocrit} = 7.778 - (0.088 \times \text{peak aortic velocity}) + (0.968 \times \text{gestational age}) - (10.911 \text{ if hydropic}) \quad \text{(I)}$$

$$\text{Hematocrit} = 45.312 - (56.261 \times \text{umbilical artery Pourcelot index}) - (0.128 \times \text{peak aortic velocity}) + (1.042 \times \text{gestational age}) \quad \text{(II)}$$

Results

The predicted hematocrits were compared to the actual hematocrits as shown (Table I, Fig. 1). Whereas formula I continued to be significantly correlated with the actual hematocrit value ($r = 0.706$, $p < 0.007$), formula II was not ($r = 0.286$, $p < 0.35$). Patients 2, 7, 8, and 10 were hydropic at the time of presentation; the others were not hydropic.

Formula I was derived from three factors: the gestational age, the peak velocity in the descending aorta, and a factor for hydrops. Each of these was independently compared to the actual hematocrit level to determine whether each was significantly related, or whether one factor was responsible for the significant correlation observed. The only significant correlation was between hydrops and hematocrit level ($p < 0.007$). The gestational age and peak aortic velocity were not significantly correlated with hematocrit value ($p = 0.51$, and $p = 0.26$, respectively).

Comment

The relationship between Doppler flow-velocity waveforms and fetal anemia has been the focus of examination for several years. Kirkinen et al.[1] first reported a close correlation between umbilical venous blood velocities and postpartum hematocrits. Griffin et al.[2] reported a weak relationship ($r = 0.5$) of uncertain clinical significance between the time-averaged maximal velocity in the descending aorta and the hematocrit. Rightmire et al.[3] similarly found in a retrospective study that a relationship was present between Doppler waveform indices and hematocrit. No prospective test of the reported relationships was performed.

An effect of anemia on Doppler waveforms might be anticipated from the pregnant ewe model. Tenenbaum et al.[8] reported that sudden increases in fetal hematocrit resulted in sustained alterations in umbilical artery flow. Our previous report failed to show any significant changes in Doppler waveforms before and after transfusion. In contrast, Fumia et al.[9] reported that fetal flow to a variety of organs, including the placenta, failed to change over a wide range of induced hematocrits. Although in cases of severe erythroblastosis the anemia and hypoproteinemia may result in reduced blood viscosity, we have not attempted such measurements. The only Doppler consequence of such a change may be reduced spectral broadening. Woo et al.[10] reported reduced spectral broadening in anemic fetuses with homozygous α-thalassemia, although this was based on subjective criteria because no generally accepted measurement is available for spectral broadening and no comparisons to fetal hematocrit were presented.

In our earlier report, we retrospectively examined the relationship between selected Doppler indices and fetal hematocrit.[4] The regression equations derived from patients before initial transfusion were highly sta-

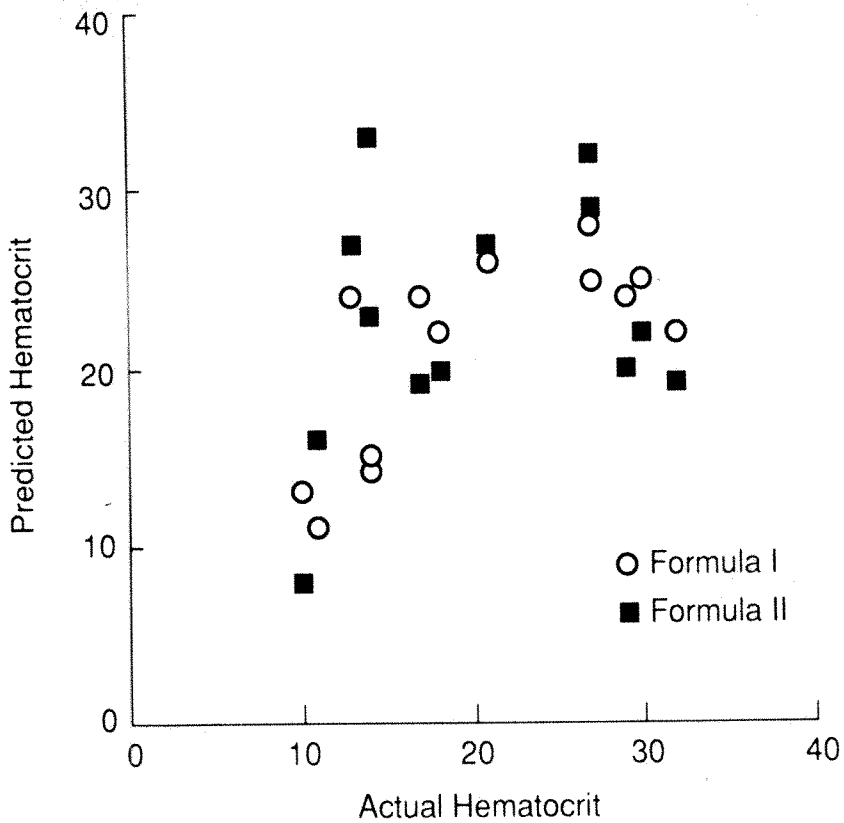

Fig. 1. Predicted and actual hematocrits. Horizontal axis shows actual hematocrits and vertical axis shows level predicted by two formulas.

tistically significant. These same equations were unable to predict hematocrit level before subsequent transfusions. Similarly, a new equation derived from the second transfusion data was unable to predict the hematocrit at third or later transfusions. This latter equation included the uterine artery pulsatility index, a surprising finding.

Our current study used the equations derived from the "first transfusion" group to examine their ability to predict the hematocrit level in a prospective fashion in patients about to undergo primary transfusions. Although the previously reported relationship between one of the Doppler-based formulas and fetal hematocrit remained significant, the second formula failed to demonstrate any statistical significance. The difference between statistical significance and clinical usefulness must be considered in further detail.

When the components of the equation were each examined for their contribution to the overall predicted hematocrit value, only the factor for presence or absence of hydrops retained significance. The correlation of hydrops and hematocrit was $r = 0.7$, whereas for hematocrit and peak aortic velocity and gestational age, poor correlation was observed ($r = 0.38$, and $r = 0.14$, respectively).

Thus it appears that the presence or absence of hydrops was the only factor responsible for the significant relationship between the formula being tested and the true hematocrit. Further confirmation of this conclusion is provided by the results obtained from the three nonhydropic fetuses included in this series whose hematocrits fell below 20% (patients 1, 5, and 6, Table I). In none of these fetuses did the predicted hematocrit value fall below 20% by formula I.

We conclude that our previously described formulas that used Doppler flow indices in the severely isoimmunized fetuses were unable to assist in the prediction of hematocrit. Prospective evaluation of any Doppler information must be an integral part of the evaluation of this new technique before its acceptance as a standard component of obstetric care. At present Doppler flow-velocity waveform indices appear to be of limited usefulness in the prediction of which isoimmunized pregnancies will require fetal transfusion, or in the timing of series of transfusions.

Concurrence of mouthing movement and rapid eye movement/non–rapid eye movement phases with advance in gestation of the human fetus

Naoki Horimoto, MD, Takashi Koyanagi, MD, Shin Nagata, MD, Hiromasa Nakahara, MD, and Hitoo Nakano, MD

Fukuoka, Japan

To evaluate whether mouthing movement in the human fetus is related to advance in gestational age and whether such movement is concurrent with rapid eye movement or non–rapid eye movement phases, 26 fetuses from 28 to 41 weeks' gestation were observed for 60 continuous minutes with real-time ultrasonography. It was evident that regular mouthing movement every 300 to 600 msec concurred with the non–rapid eye movement period, from 35 weeks' gestation to term. Random mouthing movements that occurred at a wide range of intervals from 300 msec to approximately 525 seconds were observed predominantly during the rapid eye movement period and were unrelated to advance in gestational age. These observations were discussed in relation to biologic implications. (Am J Obstet Gynecol 1989;161:344-51.)

Key words: Eye movement, mouthing movement, concurrent development, human fetus, real-time ultrasonography

Behavioral states of human neonates have been classified by means of various combinations of biophysical parameters, including electroencephalographic findings, heart rate change, the presence or absence of eye movement, regular or irregular respiratory movement, and whether the eye is closed or open.[1-6]

Regular mouthing movement was reported to occur only during quiet sleep of newborn human infants.[1, 2, 5, 7] Regular mouthing was evident even in the human fetus in utero, as observed with real-time ultrasonography.[8] However, with respect to developmental characteristics the biologic implications remain to be elucidated. The objective of this study was to elucidate the manifestation and ontogeny of various human functions, assessed in relation to correlative development of the central nervous system.

We studied the human fetus with real-time ultrasonography to determine whether mouthing movement is related to advance in gestational age and whether mouthing movement is concurrent with rapid eye movement and non–rapid eye movement phases.

Material and methods

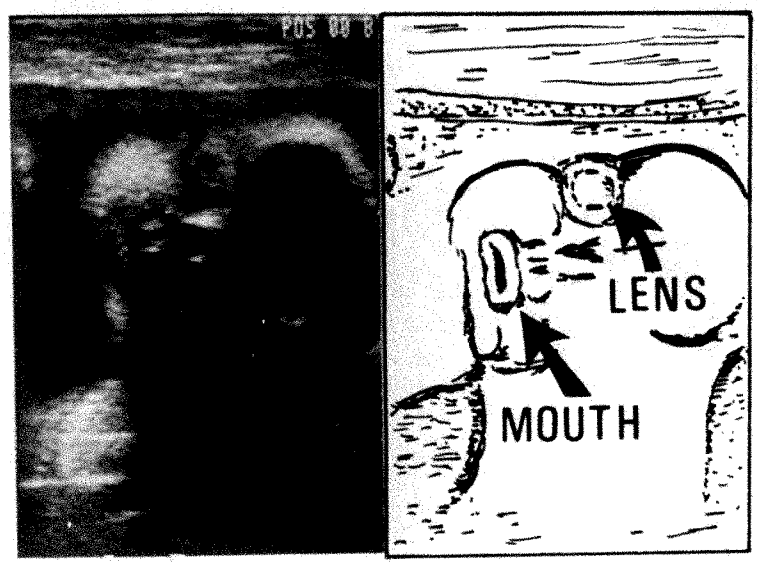

Fig. 1. Real-time ultrasonographic image and illustration used for simultaneous evaluation of eye and mouthing movements obtained from fetus at 35 weeks' gestation.

formation or intrauterine growth retardation. Each fetus was examined only once (Table I).

All mothers were cared for in the Maternity Care Unit of Kyushu University Hospital and gave informed consent to participate in this study. The period of gestation was calculated from the date of the last menstrual period and was confirmed with serial ultrasonographic measurements of crown-rump length before 11 weeks of gestation and by biparietal diameter at ≥12 weeks' gestation.

Data acquisition and processing. The ultrasonographic equipment used was an ALOKA SSD-280 model with a linear array transducer of 3.5 MHz. With the mother placed in the semi-Fowler position, the transducer was moved to obtain a simultaneous observation of the fetal eye, mouth, and jaw in one image (Fig. 1). The ultrasonographic image was continuously taken for approximately 60 minutes and simultaneously recorded on videotape with a Hitachi VT-Z70 videotape recorder in real-time fashion. When the videotape was replayed all instances of both eye and mouthing movements were marked by means of two specially devised switches that were operated independently by two different examiners. These switches were linked to a microcomputer system (NEC:PC-9801VM2). The two types of original data thus obtained were stored simultaneously on a floppy disk in an actual time sequence from the start of the recording (Fig. 2).

The eye movement from one position to another of the pair of dotted echoes, originating from both near and far margins of the lens, was defined as one unit of movement. The frequency of eye movement was calculated for every given one-minute epoch during the observation period. Rapid eye movement and non–rapid eye movement periods were regarded as those sustaining the presence and absence of movement, respectively.[9]

We defined one unit of mouthing movement as that action in which the mouth opened and returned to a closed position. The interval between two consecutive occurrences of mouthing movement was used as a parameter for subsequent analysis.

The χ^2 test was applied for analysis of fetuses divided into two groups: the gestational age group and the fetal state group. After examination of the data, age-related changes in mouthing movements of all the fetuses were retrospectively arranged into three age-groups: 5 fetuses from 28 to 31 weeks' gestation, 10 from 32 to 34 weeks' gestation, and 11 from 35 to 41 weeks' gestation. In the last group the fetal states were stratified into two

subgroups according to rapid eye movement and non–rapid eye movement periods.[9]

Accuracy of measurements in experimental system. The overall accuracy of measurements between two consecutive occurrences in a simulation experiment, from pushing the recording switch, through the analog/digital converter (MF-7016, Toitu, Ltd.) and onto storing of the information on floppy disk was evaluated with regular pulse signals created by an electric generator (FG-121B, NF Corp.). Using 200 sequential events corresponding to pulse signals at fixed rates of 500 and 1000 msec, five different examiners measured the time interval between two successive events. There were no significant interexaminer differences as determined by analysis of variance (Table II).

Results

Changes in fetal mouthing movement in relation to advance in gestational age. Fig. 3 shows chronologic changes in incidences, by percent, of the interval between two consecutive mouthing movements. The pattern of distribution was fairly uniform in all five fetuses from 28 to 31 weeks of gestation. Seven of the 10 fetuses between 32 and 34 weeks' gestation demonstrated a high percentage of incidences when the interval between mouthing movements was concentrated at a range between approximately 300 and 600 msec. The remaining three fetuses still showed a pattern of distribution similar to that found between 28 and 31 weeks' gestation (uniform). From 35 weeks of gestation to term, all 11 fetuses showed a pattern of distribution with a mound-shaped high percentage of incidence and low incidence at the interval range of <600 msec and >600 msec, respectively. Considering these chronologic changes in distribution of mouthing movement pattern, an intergroup comparison was restricted to two groups, from 28 to 31 weeks and from 35 to 41 weeks of gestation.

Fig. 4 shows the cumulative incidences of mouthing movement interval corresponding to each fetus (i.e., 5 at 28 to 31 and 11 at 35 to 41 weeks' gestation). In all fetuses before 32 weeks' gestation, the cumulative incidences rose in a slow, almost linear fashion (termed pattern I); these incidences started with intervals of 300 to 400 msec and reached a saturation point of 100% at intervals of 165 to 390 seconds. In 8 of 11 fetuses at ≥35 weeks of gestation, there was a rapid rise in cumulative incidences when the interval between mouthing movements ranged from approximately 300 to 600 msec. At the movement interval of 600 msec, the percentage of cumulative incidence ranged from 49% to 80% in these eight fetuses. This rapid rise was followed by a nearly linear slow rise as the length of the interval increased (termed pattern II). The remaining three fetuses showed pattern I activity, with cumulative incidences rising in a slow, almost linear fashion. The cumulative incidences reached 100% between about 170 and 760 seconds in fetuses at ≥35 weeks of gestation.

There was a statistical difference ($p < 0.05$) between gestational ages of 28 to 31 weeks/pattern I (5/5, 100%) and gestational ages of 35 to 41 weeks/pattern I (3/11, 27%), using the χ^2 test (Table III).

Changes in fetal mouthing movement in relation to the rapid eye movement and non–rapid eye movement periods. In 11 fetuses at ≥35 weeks' gestation, all

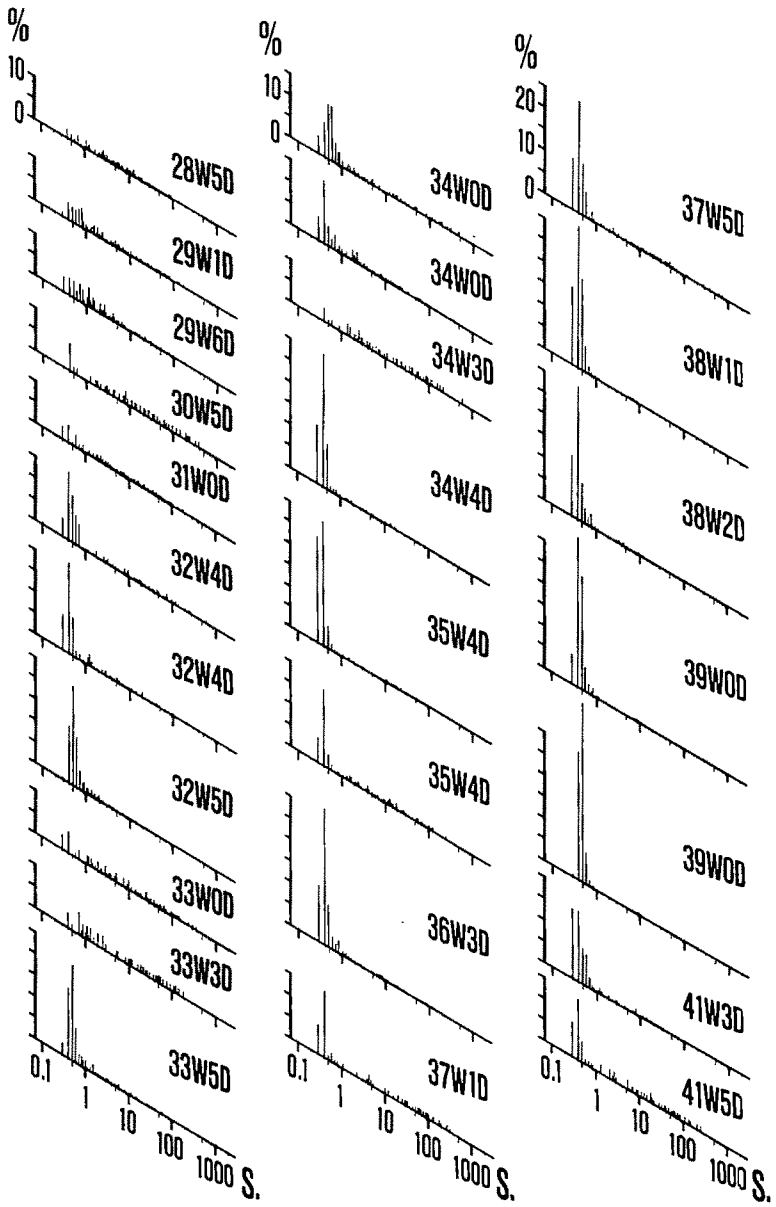

Fig. 3. Chronologic changes in interval between two consecutive mouthing movements in 26 fetuses from 28 weeks 5 days to 41 weeks 5 days of gestation. Vertical axis shows percentage of incidence at given movement interval. Horizontal axis indicates interval in seconds between two consecutive mouthing movements.

mouthing movements recorded over the entire observation period were divided into two groups according to the rapid eye movement and non–rapid eye movement periods (Fig. 5). Movements during the rapid eye movement period showed only a uniform distribution. The pattern of distribution during the non–rapid eye movement period is characterized by a mound shape, created by a high percentage of incidences at short intervals followed by low incidence with longer interval ranges.

Fig. 6 shows the cumulative incidence of the mouthing movement interval, by percent, for each case obtained and taken from the data shown in Fig. 5. During the non–rapid eye movement period, the cumulative incidence in all fetuses showed a rapid rise, ranging from an interval of approximately 300 to 600 msec followed by a nearly linear slow rise with an increase in the movement interval (pattern II). At an interval of 600 msec, the range of cumulative incidence was within 53% and 85%. During the rapid eye movement period, the cumulative incidence in all cases showed an almost linear slow rise (pattern I).

A statistical significance ($p < 0.005$) was found between rapid eye movement/pattern I (11/11, 100%)

and non–rapid eye movement/pattern I (0/11, 0%), with the χ^2 test (Table IV).

Comment

The history of studies of fetal behavioral development can be divided into two subgroups one the result of animal experiments[10, 11] and the other representing the observations of human neonates.[1, 2, 4-7] Both types of studies were extrapolated for interpretation of events occurring in the human fetus.[8, 12, 13] We used a different approach and focused directly on the human fetus in utero.[9, 14] Our objective was to evaluate the ontogeny of behavior in terms of how various fetal functions organize to become correlated and/or concurrent. We studied the concurrent development between mouthing movement and rapid eye movement/non–rapid eye movement periods with the advance in gestational age.

In all fetuses from 28 to 31 weeks of gestation, the pattern of percent-incidences of the interval between

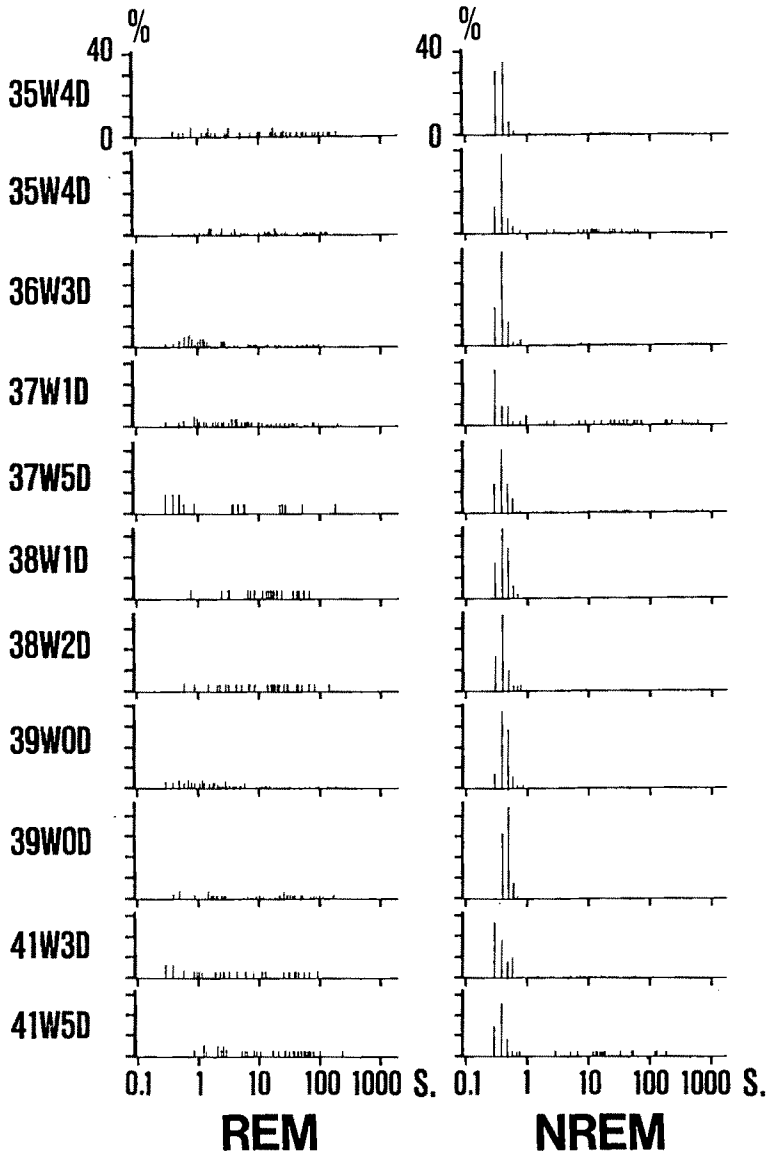

Fig. 5. Patterns of incidences of intervals of mouthing movement of fetuses from ≥35 weeks of gestation, divided into rapid eye movement and non–rapid eye movement periods (left and right columns, respectively). Data are arranged in same manner as in Fig. 3.

two consecutive mouthing movements showed a uniform distribution within the 60-minute observation period. This implies that mouthing movement occurs in a random manner during this stage of gestation. At ≥35 weeks' gestation during the rapid eye movement period, the incidence of mouthing movement was uniformly distributed and random occurrence of mouthing movement ensued. Conversely, during the non–rapid eye movement period a high incidence was noted at short intervals between movements, in which the mouthing movement was seen to repeat as a short-term, regular occurrence.

This regular mouthing concurred closely with the non–rapid eye movement period from 35 weeks of gestation to term, whereas the random mouthing movement was observed predominantly during the rapid eye movement period and was unrelated to the advance in gestational age. From 32 to 34 weeks of gestation, the patterns of the incidences of the mouthing movement intervals showed a transitional stage between 28 and 31 weeks and between 35 and 41 weeks of gestation. This corresponds to findings regarding age-related changes in the eye movement phase when rapid eye movement starts to consolidate at about 28 weeks and becomes fully manifest at 33 weeks' gestation. In addition, from 35 to 36 weeks of gestation to term, rapid eye movement and non–rapid eye movement periods occurred alternately with intervals of about 30 to 40

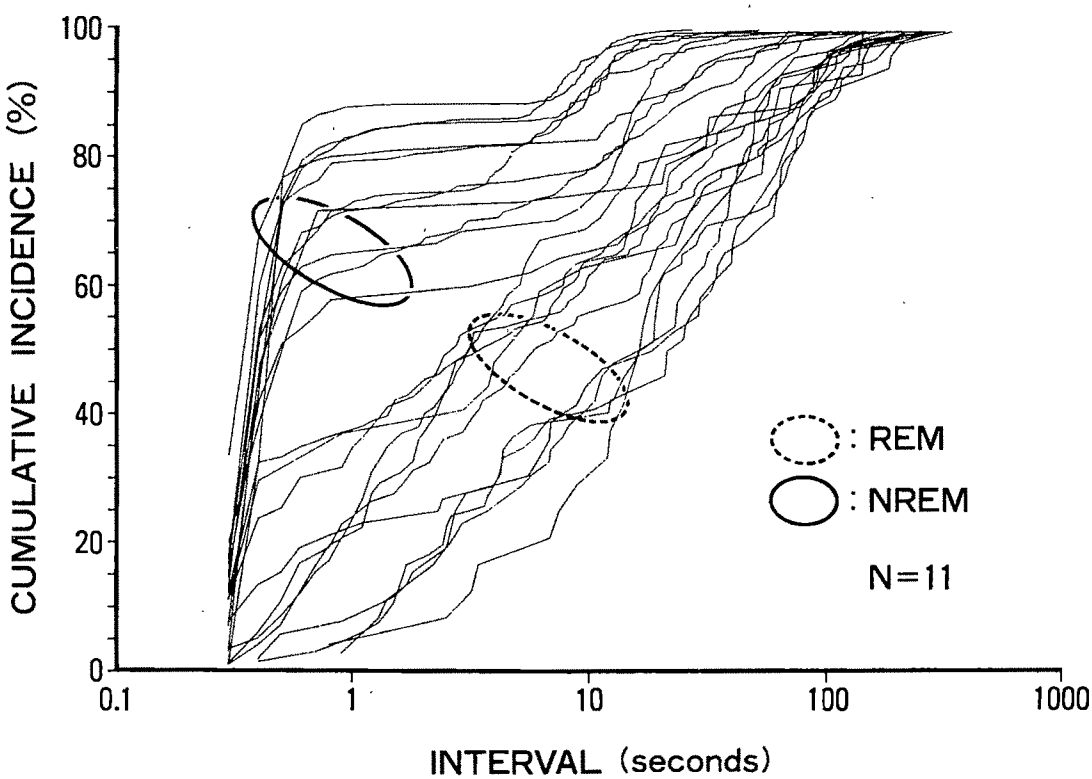

Fig. 6. Comparison of cumulative incidence of mouthing movement intervals between rapid eye movement (encircled by *dotted line*) and non–rapid eye movement (encircled by *solid line*) periods in 11 fetuses at 35 weeks of gestation to term. Data are displayed in fashion similar to that in Fig. 4.

and 20 to 30 minutes, respectively, both in the neonate[3, 6] and in the fetus.[7, 8, 13, 15]

Regular mouthing movement was observed only during non–rapid eye movement sleep in infants.[1, 2, 5, 7] In the infant delivered at or after 35 to 36 weeks of gestation, the non–rapid eye movement sleep may be an indication of functions of the thalamocortical pathway.[16] Thus the concurrence of regular mouthing with the non–rapid eye movement period suggests that the brain of a 35 to 36-week gestation fetus is functioning to the extent seen in the newborn.

In relation to behavioral states according to Prechtl's "state 1" in the neonate[5] and "state 1F" of Nijhuis et al.[8] in the fetus, these results should prove useful for evaluating brain stem function in the developing fetus.

We thank Dr. M. Inoue for data collection, M. Ohara for critical comments, L. Saza for helpful advice on the manuscript, M. Kurata for assistance with the computer analysis, and K. Akazawa for statistical analysis.

Fetal heart rate patterns in red blood cell isoimmunized pregnancies

K. H. Nicolaides, BSc, MD, G. Sadovsky, MD, and E. Cetin, MD
London, England

Fetal heart rate was monitored in 33 red blood cell isoimmunized patients at 32 to 36 weeks' gestation immediately before cordocentesis. The fetal heart rate patterns were analyzed according to 25 different classifications, and the values were related to the fetal hemoglobin concentration, oxygen tension, and oxygen content. Nonreactive, suboptimal, or pathologic fetal heart rate patterns were encountered more commonly in fetuses that were hypoxemic and anemic than in those that were normoxemic and nonanemic. However, the positive predictive value of these abnormal fetal heart rate patterns with respect to fetal anemia was 50% to 100%; the negative predictive value was 18% to 40%. (AM J OBSTET GYNECOL 1989;161:351-6.)

Key words: Fetal heart rate monitoring, cordocentesis, fetal hypoxemia, fetal anemia, red blood cell isoimmunization

In red blood cell isoimmunized pregnancies, abnormal fetal heart rate (FHR) patterns have been associated with poor perinatal outcome and with low hemoglobin concentration in samples obtained from the umbilical cord at birth.[1, 2] However, the validity of this association is questionable because of the temporal dissociation between measurement of these parameters.

This study describes the relationship between FHR patterns and hemoglobin concentration, oxygen tension, and oxygen content in blood samples obtained by cordocentesis from red blood cell isoimmunized pregnancies immediately after FHR monitoring at 32 to 36 weeks' gestation.

Patients and methods

FHR monitoring was performed immediately before cordocentesis in 33 red blood cell isoimmunized patients. The blood samples were analyzed for fetal hemoglobin concentration and blood gases. FHR monitoring was undertaken with patients in a semirecumbent position. Recordings were made at a paper speed of 1 cm/min (model 8041A, Hewlett Packard, Boblingen, West Germany). In all cases gestational age was determined by Naegele's rule and confirmed by ultrasonographic measurement of the fetal biparietal diameter at 16 to 20 weeks' gestation. None of the fetuses were hydropic at the time of cordocentesis.

Cordocentesis was performed as an outpatient procedure without maternal fasting or sedation. The umbilical cord vessel was identified as artery or vein by the intravascular injection of 200 to 400 μl of normal saline solution.[3] Fetal blood (200 μl) was collected into heparinized syringes and blood gas analysis was performed with a Radiometer ABL 30 blood gas analyzer (Copenhagen). For hemoglobin analysis, fetal blood samples (180 μl) were collected into 20 μl of isotonic edetic acid solution (0.5 mmol/L in 0.15 mmol/L sodium chloride); the hemoglobin concentation (grams per deciliter) was determined with a Coulter S Plus counter (Coulter Electronics Ltd, Luton, England). The fetal origin of blood was confirmed subsequently by Betke-Kleihauer testing. Oxygen content was calculated from

the Po_2, hemoglobin concentration, and pH using the equations of Bohr et al.[4] and Hill.[5]

In normal fetuses the hemoglobin concentration increases and the oxygen tension decreases with gestation.[6, 7] Furthermore, the oxygen content for umbilical venous blood (mean ± SD, 6.6 ± 0.6 mmol/L) is higher than that in the umbilical artery (mean ± SD, 5.8 ± 1.1 mmol/L).[7] Therefore, in each red blood cell isoimmunized pregnancy, the fetal hemoglobin concentration was subtracted from the normal mean for gestation to calculate the degree of anemia. The oxygen tension and oxygen content were expressed as the number of standard deviations by which the observed values differed from the corresponding normal means for gestation for the appropriate vessel sampled.

FHR analysis. The FHR traces were examined by two observers who were unaware of the indications for fetal blood sampling or of the blood gas and hemoglobin results. The traces were divided into recordings of 1-minute intervals; each interval was examined for FHR baseline, oscillation amplitude, and oscillation frequency. The amplitude and duration of each increase (acceleration) and decrease (deceleration) from the baseline were also recorded. FHR tracings were classified as *reactive* or *nonreactive*, on the basis of the presence or absence of FHR accelerations according to 17 different definitions. Thus a reactive trace was one in which there were 1 to 5 accelerations of 10 to 15 beats/min, lasting for 15 to 30 seconds during a period of 10 to 60 minutes (Table I). Tracings also were classified as *normal, suboptimal,* or *pathologic* on the basis of baseline, baseline variability (oscillation amplitude and oscillation frequency) and the presence or absence of accelerations or decelerations, according to eight quantitative or descriptive scoring systems.[1, 8-14] Each system has different criteria of normality and abnormality. For example, Fischer et al.[12] define a normal baseline variability by the presence of an oscillation frequency of at least 6 cycles/min (cpm), whereas Hammacher et al.[10] accept 2 cpm as normal. Similarly, Lyons et al.[14] consider the absence of at least four accelerations of at least 15 beats/min during a 20-minute period of recording to be a pathologic feature; Kubli and Rutgers[9] ignore accelerations in their scoring system. In the statistical

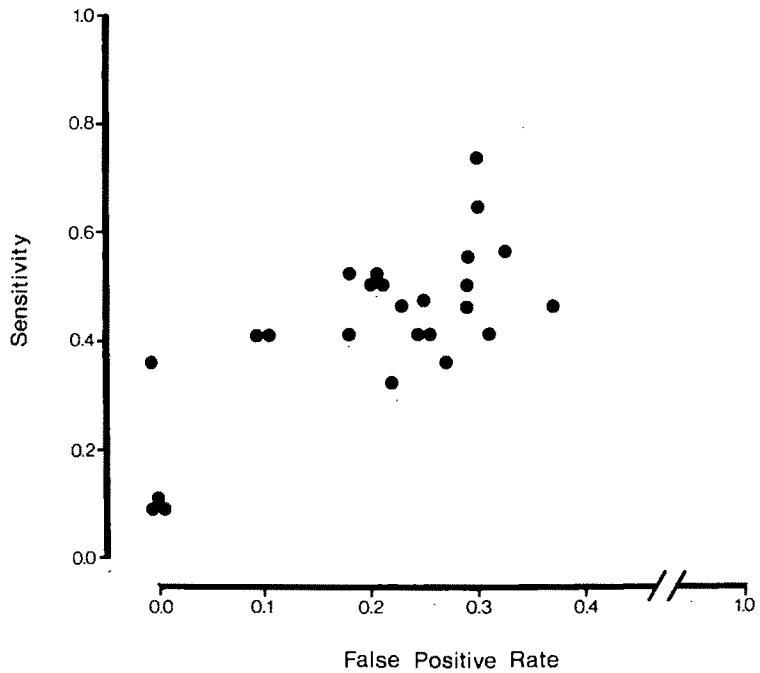

Fig. 1. Sensitivity and false-positive rates of 25 classifications of FHR patterns in predicting fetal oxygen content deficit in rhesus-isoimmunized pregnancies.

analysis of the data from the scoring systems, suspicious, suboptimal, prepathologic, and pathologic classifications were grouped together as abnormal.

Results

In the 33 red blood cell isoimmunized pregnancies, the ranges in fetal hemoglobin concentration, oxygen tension, and oxygen content were +1.7 to −10.1 gm/dl (+0.8 to −2.9 and +1.0 to −7.0 SD) from the respective normal means for gestation (Table II). The classification of the FHR pattern in each case as reactive or nonreactive and normal, suboptimal, or pathologic is shown in Table II.

Nonreactive traces were more commonly encountered in severely anemic and hypoxemic fetuses. However, there were large variations in the sensitivity and specificity of FHR patterns in the prediction of fetal oxygenation or hemoglobin concentration (Table III). Thus, when the criteria for reactivity are lenient (one acceleration of 10 beats/min, lasting for 10 seconds during 60 minutes of recording), only two extremely anemic (hemoglobin deficit, 10.1 gm/dl) fetuses had nonreactive FHR patterns (sensitivity, 10%; specificity, 100%). With use of more stringent criteria (a minimum of five accelerations during 20 minutes of recording), the FHR patterns were nonreactive in 24 of the 33 (73%) fetuses, and the sensitivity and specificity of predicting anemia were 68% and 18%, respectively. The sensitivity and specificity of most classifications improved when the predicted parameter was fetal Po_2 or oxygen content rather than hemoglobin concentration (Table III). A receiver-operating characteristic plot is shown in Fig. 1.

Pathologic FHR patterns were observed in 10 of the 11 fetuses with an oxygen content at least 4 SD below the normal mean. In two of these fetuses the hemoglobin was normal but the Po_2 was below the 2.5th percentile of the normal range.

Sinusoidal FHR pattern (frequency 3 cpm, amplitude 6 beats/min, duration, 100 of 120 minutes of recording) was observed in only one severely anemic fetus (case 1, Table II).[1, 2]

Comment

This study examines the relationship between fetal blood hemoglobin concentration, oxygen tension, or oxygen content and FHR patterns in the undisturbed fetus from red blood cell isoimmunized pregnancies. The minimum gestational age of 32 weeks was selected because both normal and pathologic FHR patterns exhibit a gestation-related "maturation."[15, 16] The majority of published classifications of normality or abnormality are based on data derived from pregnancies of at least 32 weeks' gestation.

Previous reports of FHR patterns in red blood cell isoimmunized pregnancies have focused on the association between fetal compromise and sinusoidal FHR patterns. Thus Rochard et al.[1] evaluated antenatal FHR in 50 red blood cell isoimmunized pregnancies and reported the presence of sinusoidal FHR patterns in 20

cases; 18 of the fetuses were hydropic and 10 died in utero or during the neonatal period.[1] Similarly, in a review of 42 cases of red blood cell isoimmunized pregnancies at 33 to 38 weeks' gestation, sinusoidal and/or decelerative FHR patterns were observed within 5 days of delivery in 12 cases; the umbilical cord hemoglobin concentration at birth was 3 to 12.3 gm/dl. In contrast, the FHR patterns were normal in 30 cases with cord hemoglobin concentrations of 9.6 to 20.9 gm/dl. It was concluded that FHR monitoring is an excellent tool for detecting fetal anemia.

Our study suggests that a sinusoidal FHR is observed only in association with extreme fetal compromise, since it was present in one of the two most anemic and hypoxemic fetus (hemoglobin concentration deficit, 10.1 gm/dl; oxygen content, 5 SD below the normal mean). Lesser degrees of anemia were associated with decreased FHR reactivity and baseline variability as well as the development of decelerations. Thus nonreactive, suboptimal, or pathologic FHR patterns were more commonly observed in the anemic (hemoglobin deficit >2 gm/dl) than nonanemic fetuses (Table II). However, there is a large overlap in values. Therefore in the clinical management of red blood cell isoimmunized pregnancies examination of FHR patterns cannot predict accurately the degree of fetal anemia. As expected, there was a trend of increased sensitivity with reduced specificity as the criteria for normality of FHR became more stringent (Table III, Fig. 1).

The observation that pathologic FHR patterns were more closely related to fetal oxygenation than to hemoglobin concentration (Table III) is consistent with the physiology of the fetal cardiovascular system. The medulla oblongata, which controls cardiac activity through the autonomic nervous system, is influenced by afferents from peripheral chemoreceptors and by the direct action of carbon dioxide and hydrogen ions. The association between pathologic FHR patterns and low fetal blood oxygen content is presumably the result of tissue hypoxia in the medulla oblongata, whereas that between pathologic FHR patterns and low Po_2 is the result of stimulation of peripheral chemoreceptors.

This study establishes that in the management of red blood cell isoimmunized pregnancies, the present criteria of normality or abnormality of FHR patterns do not allow for an accurate prediction of the degree of fetal anemia. However, fetal anemia is associated with pathologic FHR patterns. The association is more likely to be mediated by the accompanying disturbance in fetal oxygenation than by the hemoglobin deficit.

Plasma atrial natriuretic peptide in human fetus: Response to intravascular blood transfusion

Marios Z. Panos, MD, Kypros H. Nicolaides, MD, John V. Anderson, MD, Demetrios L. Economides, MD, Lesley Rees, MD, and Roger Williams, MD

London, England

To investigate whether atrial natriuretic peptide is present in the human fetal circulation and changes in response to fetal blood volume expansion, the concentration of plasma atrial natriuretic peptide was measured by radioimmunoassay in samples obtained by cordocentesis. Twenty-four patients referred for intravascular blood transfusion because of red cell isoimmunization at 21 to 35 weeks' gestation were studied. Plasma atrial natriuretic peptide concentrations in fetal blood (median, 8.0 pmol/L; range, 1 to 27.3) were significantly higher than those of 25 young 18- to 32-year-old adult control subjects (median, 4.5 pmol/L; range, 1 to 11.3, $p < 0.002$ but similar to those found in the umbilical cord blood of 10 normal neonates immediately after delivery (median, 7.35 pmol/L; range, 2.7 to 15.5). In seven patients in whom fetal and maternal plasma atrial natriuretic peptide was measured simultaneously, all fetal concentrations were higher ($p < 0.01$). The concentration of fetal atrial natriuretic peptide before and immediately after blood transfusion ($n = 12$) rose significantly ($p < 0.05$), and the rise correlated positively with the transfusion rate ($p < 0.05$). We conclude that atrial natriuretic peptide is present in plasma of the human fetus as early as 21 weeks' gestation and that its concentration increases promptly in response to vascular volume expansion. These findings suggest that atrial natriuretic peptide may play a role in fetal volume homeostasis. (Am J Obstet Gynecol 1989;161:357-61.)

Key words: Atrial natriuretic peptide, fetal blood, volume expansion, cordocentesis

Atrial natriuretic peptide is a natriuretic and diuretic substance that suppresses the activity of the renin-aldosterone system and has a vasodilator action.[1] It is secreted by the cardiac atria in response to rises in atrial pressure through atrial wall stretch and thus appears to have a role in blood volume regulation.[1] In adults, plasma concentration of atrial natriuretic peptide has been shown to rise in response to central volume expansion as induced by intravenous infusion of saline sodium, postural change, and headout water immersion.[1,2] Whether physiologic levels of atrial natriuretic peptide affect volume homeostasis has been debated, although recent data suggest that atrial natriuretic peptide affects short-term regulation of sodium excretion.[3] It is not known whether atrial natriuretic peptide is involved in blood volume homeostasis in intrauterine life. The aim of the present study was to examine whether atrial natriuretic peptide is present in the circulation of the human fetus, and if so, whether its circulating levels change in response to fetal blood volume expansion.

Patients and methods

Twenty-four normotensive pregnant women (21 to 35 weeks' gestation), ages 18 to 39 years, referred for intravascular blood transfusion because of severe red cell isoimmunization, were studied. None of the fetuses was hydropic, as judged by ultrasound examination. Cordocentesis was performed as an outpatient procedure without maternal fasting, sedation, or fetal paralysis.[4] Pure fetal blood (3 ml) was aspirated from the umbilical vein into heparinized syringes for fetal hemoglobin, blood gases, and atrial natriuretic peptide measurement just before intravascular blood transfusion. Packed blood compatible with that of the mother (taken from the donor 24 to 36 hours earlier) was infused into the fetal circulation.[5] At the end of the transfusion, the needle was flushed with 1 ml of normal saline solution, and after 1 minute to allow for equilibration, an additional 1 ml sample was aspirated and discarded, and 0.2 ml was obtained for hemoglobin measurement. In 12 patients an additional 2.2 ml of fetal blood was aspirated for atrial natriuretic peptide assay. The fetal heart rate was monitored throughout the transfusion, and none of the procedures was complicated by fetal bradycardia. Transfusions were timed. In seven patients maternal blood was taken from an

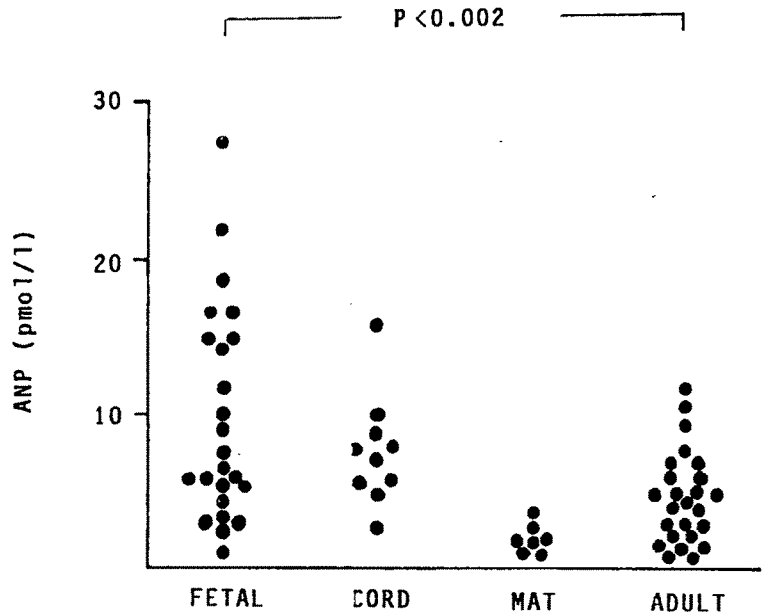

Fig. 1. Plasma atrial natriuretic peptide *(ANP)* concentration in fetal umbilical vein at 21 to 35 weeks' gestation *(FETAL)*, umbilical cord vein at full-term delivery of normal neonates *(CORD)*, maternal plasma *(MAT)*, and normal 18- to 32-year-old adults *(ADULT)*.

antecubital vein before and after fetal blood transfusion.

For comparison, blood was taken for atrial natriuretic peptide assay from the umbilical cord vein at birth of 10 neonates of normal full-term pregnancies within 5 minutes of delivery of the placenta. Plasma atrial natriuretic peptide concentration was also measured in 25 nonpregnant adult volunteers, ages 18 to 32 years. Venous blood samples were taken from an antecubital vein at 9:00 AM, while sitting (30 minutes) after an overnight fast. Plasma from donor blood was separated just before transfusion and assayed for atrial natriuretic peptide.

All samples were collected into chilled heparinized tubes and centrifuged at 4° C for 10 minutes within 10 minutes of collection. Plasma was stored at −20° C until assayed. Fetal hemoglobin was measured on a Coulter Counter S-Plus system (Coulter Electronics Ltd., Luton, United Kingdom) and blood oxygen tension (Po_2) on Radiometer ABL 30 (Radiometer, Copenhagen, Denmark).

Atrial natriuretic peptide immunoreactivity in plasma was measured after plasma extraction by means of a modification of a previously described radioimmunoassay procedure.[6] A new rabbit atrial natriuretic peptide antiserum was used (YB8) that increased the assay sensitivity to 0.3 fmol/tube, which allowed smaller samples to be processed. This modified assay procedure detects amounts of atrial natriuretic peptide immunoreactivity in plasma extracts not significantly different from values measured with an older, less-sensitive antiserum (Y2) in identical samples. Antiserum YB8 was used at a titer of 1 in 6400, at which 50% binding occurred. Otherwise the assay conditions were identical to those described earlier for antiserum Y2[6] except that a 10-point standard curve of 0.25 to 25 fmol of synthetic human α atrial natriuretic peptide was used. Human plasma extracts caused displacement of binding in the YB8 assay in parallel with that caused by pure synthetic α human atrial natriuretic peptide. Fragment testing revealed antiserum YB8 to bind to the central part of the atrial natriuretic peptide molecule with negligible binding to carboxy- and aminoterminal atrial natriuretic peptide fragments. For adult samples, 3 ml of plasma was extracted on Sep-Pak C-18 cartridges (Millipore, Bedford, Mass.). The retained peptides were eluted with 2 ml of 60% acetonitrile containing 0.1% trifluoracetic acid, lyophilized in 1.2 ml of radioimmunoassay buffer. Aliquots (200 μl) were assayed in duplicate. One milliliter fetal plasma samples were treated similarly but reconstituted in 900 μl of buffer. Three hundred microliter aliquots were assayed in duplicate and 100 μl aliquots in singlet. Assay sensitivity was equivalent to 0.3 pmol/L in adult plasma and 1 pmol/L in smaller-volume fetal samples. Intra-assay variation was 9% and interassay variation was 11%. Mean ± SEM recovery of atrial natriuretic peptide immunoreactivity from the Sep-Pak extraction step was 79% ± 2% for the adult plasma samples and 74% ± 4% for the smaller fetal samples. Results are presented as measured without correction for extraction recovery.

The volume of blood neccesary for transfusion was

calculated from the expected fetoplacental blood volume (adjusted for gestation) and the pretransfusion and donor hemoglobin concentrations.[7] The fetoplacental blood volume after each transfusion was calculated from the change in fetal hemoglobin concentration and the volume and hemoglobin concentration of the transfused blood.[8] Rate of transfusion was calculated from the duration and volume of blood transfused. Since fetal hemoglobin and umbilical venous Po_2 change with gestation, these were expressed as a difference from the normal means for gestation, δ hemoglobin gm/dl and δ Po_2 mm Hg, respectively.[7, 9]

Statistical analysis was by the Wilcoxon two-sample rank sum test and the Wilcoxon signed rank test for paired values as appropriate. Tests of correlation were by the Spearman rank test. The level of statistical significance was taken as $p \leq 0.05$. The study was performed with approval from the King's College Hospital Ethical Committee.

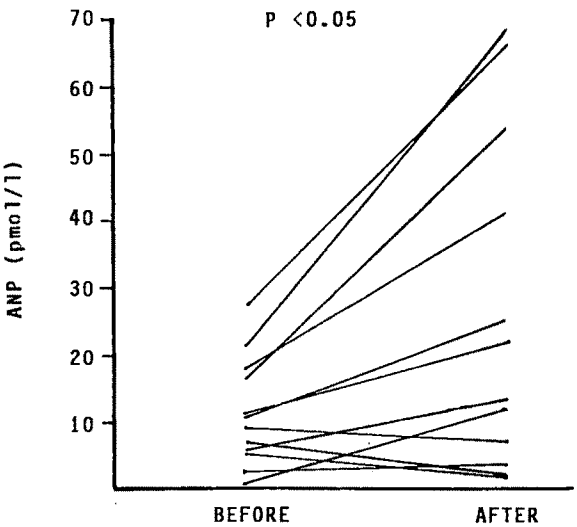

Fig. 2. Plasma atrial natriuretic peptide *(ANP)* concentrations before and immediately after intravascular blood transfusion in 12 fetuses with red cell isoimmunization.

Results

Intravascular blood transfusion was completed in all cases, and there were no complications. Basal atrial natriuretic peptide concentration was significantly higher in the fetus (median, 8.0 pmol/L; range, 1 to 27.3) than in 18- to 32-year-old nonpregnant adults (median, 4.5 pmol/L; range, 1 to 11.3, $p < 0.002$) and not significantly different from umbilical cord blood values after delivery (median, 7.35 pmol/L; range, 2.7 to 15.5) (Fig. 1). There was no correlation between length of gestation and basal fetal concentration of atrial natriuretic peptide. In the seven patients in whom paired fetal and maternal blood samples were taken, fetal plasma atrial natriuretic peptide concentrations (median, 16.5; range 5.8 to 27.3) were higher than the corresponding maternal atrial natriuretic peptide concentrations in all cases (median, 1.5 pmol/L; range, 1 to 3.3, $p < 0.01$). There was no correlation between basal δ Po_2 or δ hemoglobin (median, 2.4 mm Hg; range, −24.4 to 11.37 and median −3.2 gm/dl; range, −7.88 to 0.8 gm/dl, respectively), and basal atrial natriuretic peptide concentration, which suggests that oxygen tension or the degree of anemia did not influence basal fetal atrial natriuretic peptide levels.

Atrial natriuretic peptide was not detectable in donor blood. Fetal transfusions lasted between 3 and 16 minutes (median, 7.45), and the rate of transfusion was between 4.26 and 18.57 ml/min (median, 11.65). Volume of blood transfused expressed as a ratio of the estimated fetoplacental volume was 0.29 to 1.37 (median, 0.76). There was a significant increase in fetal atrial natriuretic peptide concentrations after transfusion ($p < 0.05$) (Fig. 2.), with a positive correlation between the rate of transfusion and change in atrial natriuretic peptide concentration ($p < 0.05$). There was no correlation either between the volume of blood transfused or the rate of expansion of the estimated fetoplacental blood volume and the change in fetal atrial natriuretic peptide concentration. There was no significant difference in the plasma atrial natriuretic peptide concentration of the paired maternal samples taken before and after intravascular blood transfusion ($n = 7$).

Comment

A previous study[10] reported that atrial natriuretic peptide was detectable in human umbilical cord blood. Our study concurs with this report and goes further to show that atrial natriuretic peptide is present in fetal plasma in considerable concentrations as early as 21 weeks' gestation. The demonstration of an increase in fetal atrial natriuretic peptide concentration after fetal blood volume expansion suggests that the mechanisms governing its release in the fetus are similar to those operating in adults.[1] Whether the observed rise in atrial natriuretic peptide after intravascular blood transfusion was enough to cause a natriuresis or an increase in venous capacitance in the fetus is not shown by the present study and will require further investigation. However, in the ovine fetus intravascular infusion of saline solution increases glomerular filtration rate and decreases fractional sodium reabsorption, findings consistent with previous reports of renal actions of atrial natriuretic peptide in adults.[1, 11, 12] Studies of fetal volume homeostasis in animals have demonstrated that changes in maternal hydration cause short-term changes in fetal blood volume through transplacental water exchange, with corresponding changes in fetal arginine-vasopressin and urine and lung fluid

flows.[13, 14] Collectively, these findings allow us to postulate that fetal atrial natriuretic peptide may act in a manner complementary to that of fluid-conserving hormones to protect the fetal blood volume from overexpansion.

Concentrations of atrial natriuretic peptide in the fetus were higher than in maternal plasma and adult control subjects, ages 18 to 32 years, but similar to those found in the umbilical cord blood of normal babies immediately after delivery. It is possible that the similarity between fetal umbilical vein concentrations of atrial natriuretic peptide and full-term umbilical vein concentrations after delivery may be fortuitous because of the longer gestation in the latter. Even though no hydrops was noted on ultrasound examination, it is possible that some fetuses may have been on the verge of "high output" heart failure, and this might account for the relatively high plasma concentrations of atrial natriuretic peptide in fetuses. The present results are consistent with the recent finding of a greater than twofold concentration of atrial natriuretic peptide in the plasma of healthy ovine fetuses compared with that of maternal plasma.[11] Messenger ribonucleic acid coding for the atrial natriuretic peptide prohormone is now known to be present in increased concentration in fetal cardiac ventricles compared with ventricles of normal adults,[15] and it is possible that release of atrial natriuretic peptide from the fetal ventricle contributes to the higher plasma concentrations of atrial natriuretic peptide found in the fetus.

The higher circulating levels of atrial natriuretic peptide in the fetus could be attributed either to an increase in secretion or reduced breakdown. The latter seems unlikely, since the ovine fetus has been shown to have a rapid clearance rate of plasma atrial natriuretic peptide.[12] On the other hand, hemodynamic and endocrine conditions in the fetus favor increased secretion of atrial natriuretic peptide: fetal cardiac output is proportionately increased compared with that of adults,[16] and increased plasma concentrations of glucocorticoids, progesterone, and aldosterone are known to be present in the fetal circulation. All these factors are known to potentiate atrial natriuretic peptide secretion.[1]

The significant rise in fetal plasma atrial natriuretic peptide concentration after transfusion did not correlate with volume of blood transfused or estimated fetoplacental volume expansion. This finding contrasts with animal data from a study of healthy ovine fetuses. Ross et al.[11] showed a positive correlation between volume of saline solution infused into the ovine fetal circulation and increase in atrial natriuretic peptide. Circulating atrial natriuretic peptide began to rise 10 to 20 minutes after the start of the infusion and reached a maximum at 40 minutes, a delay similar to that observed in human adults.[2] It is possible that the discrepancy between our findings in the human fetus and those in the ovine fetus[11] is the result of the timing of fetal blood samples after transfusion, which, for ethical reasons, were taken immediately after completion of transfusion when maximal levels of atrial natriuretic peptide may not have been reached. The positive correlation between the rate of infusion and rise in atrial natriuretic peptide is in agreement with findings of previous studies on the effects of saline solution infusion given at varying rates in young adults.[2] The increase in fetal atrial natriuretic peptide concentration after transfusion despite high basal levels demonstrates that the fetus retains significant atrial natriuretic peptide reserves.

In conclusion, atrial natriuretic peptide is present in the human fetal circulation as early as 21 weeks' gestation, and its concentration rises in response to blood volume expansion. These findings support the hypothesis that plasma release of atrial natriuretic peptide in the fetus may play a role in fetal blood volume homeostasis.

New Haven, Connecticut

The mechanism of development of hydrops fetalis in severe isoimmunization has been subject to speculation. We performed pulsed Doppler assessment of cardiac output in 13 severely isoimmunized fetuses before and after intravascular transfusion and compared the results with 37 control fetuses between 20 and 34 weeks' gestation. The cardiac index of the anemic fetuses was significantly greater than that of the control group. A significant (right ventricle, $p < 0.01$; left ventricle, $p < 0.02$) increase in indexed output was noted from both ventricles and in the combined ventricular output (mean ± SEM 644 ± 35.3 ml/kg/min in control fetuses versus 879 ± 86.0 ml/kg/min in anemic fetuses, $p < 0.006$). An increase in cardiac output was also noted when anemic fetuses were compared with gestational age–specific norms. We conclude that severely anemic fetuses of isoimmunized pregnancies tend to have significantly higher cardiac output than do unaffected fetuses and that this high output state may play a part in the development of hydrops fetalis. (Am J Obstet Gynecol 1989;161:361-5.)

Key words: Prenatal diagnosis, fetal therapy, isoimmunization, Doppler ultrasound, cardiac output, intrauterine transfusion

The mechanism for the development of hydrops fetalis in the anemic, isoimmunized fetus remains the subject of speculation. Among the mechanisms proposed are anemia with secondary cardiac pump failure and increased venous pressures, hypoproteinemia with low colloid osmotic pressure, portal hypertension caused by extramedullary hematopoiesis, and high output cardiac failure.

Although the studies of Phibbs et al.[1] suggest that the blood volume of erythroblastotic infants at birth is not generally elevated, careful study of the cardiac output of severely anemic fetuses has not been carried out. We have performed a series of intravascular fetal transfusions on severely isoimmunized fetuses.[2,3] On the basis of previous observations that support the concept that nonimmune hydrops represents congestive heart failure in the fetus and that cardiac Doppler waveform changes could be observed in fetuses with hydrops caused by tachyarrhythmias,[4,5] we have pursued further investigation of the mechanism of hydrops fetalis using pulsed Doppler flow analysis. The present study examines the cardiac output, as measured by pulsed Doppler ultrasound studies, of fetuses with severe anemia caused by isoimmunization.

Material and methods

Thirty-five nonanemic fetal patients underwent a single examination at the time of fetal echocardiography

Table I. Clinical comparison of control and isoimmunized groups

	Control (N = 37)	*Isoimmunized (N = 11)*	*p*
Gestational age (wk)			NS*
20-23.9	9	2

for routine indications between 19 and 34 weeks' gestation (mean, 28.2 weeks; SD, 5.0). These fetuses made up the control group. All had normal anatomic studies and uncomplicated pregnancies. The control and isoimmunized groups were similar in relevant demographic characteristics (Table I). For both control and isoimmunized groups, all studies were carried out by one of the authors (J. A. C.) after informed consent was obtained for participation in this study, which was performed in accordance with a protocol approved by the institutional Human Investigation Committee.

The anemic study group was drawn from 37 patients with isoimmunization caused by rhesus or other antibodies who were referred to the Yale Perinatal Unit for intrauterine intravascular transfusion. Thirteen fetuses were examined before any intrauterine treatment. The transfusion procedures and patient population have been described separately.[2, 3] Pulsed Doppler echocardiography was performed within 24 hours before and 12 hours after transfusion.

The initial examination consisted of a survey of fetal anatomy, biometry, and evaluation for the presence or absence of hydrops (defined for this study as at least two of the following: ascites, pleural or pericardial effusions, or skin edema). Fetal weight was estimated on the basis of biparietal diameter and abdominal circumference.[6] If fetal ascites was present, fetal weight was estimated by using a mean for gestational age by last menstrual period, which was confirmed by biometric measurements, including consideration of the biparietal diameter and multiple long bones. All of the anemic fetuses had accurate menstrual dating as confirmed by these sonographic criteria. Patients were studied in the Sims' position, with right hip elevation used for those who reported discomfort in the supine position.

Complete fetal echocardiographic examination was undertaken with the use of standard tomographic planes. Anatomy was normal in all studied patients. All studies were recorded on videotape and analyzed separately. Measurement of the atrioventricular valve diameters was accomplished from recordings of a four-chamber view of the heart in real time, with the ultrasound beam as close as possible to perpendicular to the interventricular septum. Structural recordings were made by means of a 5 MHz-phased array sector transducers (model HP 77020A, Hewlett-Packard, Andover, Mass.). Videotaped real-time images were played back at slow speed and frozen at maximal valve leaflet separation and then measured at a point just apical to valve insertion into the annulus, where the leaflets could be seen extending parallel to each other. At least four measurements were obtained for each valve during fetal apnea.

Table II. Transatrioventricular valve flow*

	Control	*Isoimmunized*	*p*
Tricuspid valve	361 (20.8)	489 (49.8)	<0.01
Mitral valve	284 (17.8)	390 (43.7)	<0.02

*Values are milliliters per kilogram per minute (± SEM).

Pulsed Doppler information was obtained with an apical four-chamber view of the fetal heart, with the ultrasound beam as close as possible to parallel to the plane of the interventricular septum. Doppler interrogation of the atrioventricular valves was carried out just below the valve annulus. Angle correction was applied assuming that inflow was parallel to the ventricular septum. Instruments used were specifically calibrated by the manufacturers to comply with current Food and Drug Administration acoustic output limitations with I(SPTA) below 94 mW/cm² (Model HP 77020A, Hewlett-Packard; ATL UltraMark 4, Advanced Technology Laboratories, Bothell, Wash.).

Analysis of Doppler waveforms was accomplished from videotaped waveforms digitized on a VAX workstation (Digital Equipment Corp., Maynard Mass.) by means of software developed by one of the authors (C. C. J.). Mean flow velocity across the atrioventricular valves was calculated by digitizing the maximal envelope of the waveform and applying a correction factor of 0.7.[7] All waveforms used had minimal spectral broadening (plug flow). Stroke volume was calculated by multiplying mean velocity by valve area (derived from the two-dimensional image, assuming a circular valve orifice). Cardiac output was calculated by multiplying stroke volume times fetal heart rate.

Group means were compared by the *t* test. For multiple comparisons, analysis of variance was used.

Results

Thirty-seven studies were carried out on 18 isoimmunized fetuses (range, 1 to 5 studies per patient) between 21 and 35 weeks' gestation (mean, 29.1 ± SD

Table III. Components of cardiac output and index calculations in control and isoimmunized groups*

	Control (N = 35)	*Isoimmunized (N = 11)*	*p*
Tricuspid			
Heart rate	138 (1.69)	143 (4.22)	NS
Diameter (mm)	8.5 (0.32)	8.9 (0.57)	NS
Output (ml/min)	402 (36.3)	502 (72.4)	NS
Index (ml/min/kg)	361 (20.8)	489 (49.8)	< 0.01
Mitral			
Heart rate	140 (1.86)	143 (4.22)	NS
Diameter	7.8 (0.29)	8.4 (0.45)	NS
Output	302 (24.2)	382 (41.0)	NS
Index	284 (17.8)	390 (43.7)	< 0.02
Combined output (index)	644 (35.5)	879 (86.0)	< 0.006

*Values given are mean (± SEM)

Table IV. Stroke volumes and ventricular outputs of control and isoimmunized fetuses matched for gestational age*

	Control	*Isoimmunized*	*p*
RV stroke volume	104 (5.6)	186 (24.4)	< 0.0001
LV stroke volume	104 (4.7)	229 (67.3)	< 0.002
Combined stroke volume	103 (4.6)	203 (40.1)	< 0.0001
RV output	105 (5.7)	192 (26.9)	< 0.0001
LV output	104 (4.9)	234 (74.2)	< 0.003
Combined output	104 (4.9)	208 (44.0)	< 0.0002

RV, Right ventricular; *LV*, left ventricular.
*Values are percent predicted, mean (± SEM).

3.7). Thirteen studies were performed before the first intravascular transfusion of that pregnancy; the remainder were performed on patients undergoing second or subsequent transfusions. Of the 13 patients, two were studied before initial transfusions; their results were markedly higher than any other patients in either group (combined ventricular outputs of 1391 and 2380 ml/min/kg). The studies of these patients were performed at relatively high incident angles (40 and 60 degrees), introducing potential error into the flow estimate. To avoid any skew in the data resulting from exaggeration of the isoimmunized group results by these two patients, they have been removed from comparisons with the control group. Therefore the remaining analysis involves a comparison of 11 patients studied before initial intravascular transfusion.

Transatrioventricular valve flow from each ventricle and combined ventricular output are shown in Table II. Each ventricle's output when indexed to estimated fetal weight was significantly higher than that of the control group. The combined indexed ventricular output of the isoimmunized group was similarly significantly elevated.

Because several factors contribute to the final measurement of flow, we examined these in the two groups. As already noted, the gestational ages and estimated fetal weights were similar in the two groups. Table III shows the valve diameters, mean velocities, and heart rates of the two groups. The two groups did not differ significantly in any of these variables, although there was a tendency, albeit not at a level of statistical significance, for each of the measured factors except for estimated weight to be higher in the anemic state.

To provide another means of comparison of the two groups independent of fetal weight, which might have been inaccurately estimated in the hydropic fetuses, the cardiac output of our normal population was expressed relative to gestational age. The stroke volume (milliliters) and ventricular output (milliliters per minute) of the anemic fetuses could then be compared with age-matched control fetuses. Table IV shows the differences between the two groups expressed as a percentage of predicted in the control group. The anemic fetuses had significantly greater stroke volumes and ventricular outputs than those predicted for gestational age.

Comparison of the right and left ventricular outputs before and after transfusion failed to show any significant changes. Comparison of the indexed flow was similar. However, one patient was notable for an increase of approximately 50% in the flow. This patient, who is reported on in greater detail elsewhere,[3] had a bradycardic, terminally hydropic fetus, whose cardiac output was 444 ml/min/kg (1.5 SD below the mean for isoimmunized fetuses and the lowest of any fetus in the group). Fetal activity improved after transfusion, but 2 weeks later porencephaly and diffuse cortical atrophy

were noted. No further transfusions were requested by the parents.

Comparison of cardiac output to fetal hematocrit failed to demonstrate any significant correlation between the hematocrit and either ventricle's flow or the combined ventricular output.

The right and left ventricular outputs were compared with each other. In the control group the right to left ventricular output ratio was 1.33, which is similar to values reported by others.[8-11] In the anemic group the ratio was 1.31.

Comment

Fetal hydrops has been postulated to occur as the result of a number of influences. Anemia leading to congestive heart failure and increased venous pressure,[1] low plasma oncotic pressure,[1] or anemia and hypoproteinemia complicated by hypoxia[12] have been implicated as etiologic agents. To date only one case report has appeared comparing cardiac output in anemic fetuses to normal fetuses.[13] That study showed no difference between a control population and a severely anemic fetus (hematocrit, 7.5%).
